VOL. LXXV. NEW YORK, SATURDAY, JULY 1, 1899. NO. 1.

ORIGINAL ARTICLES.

A COLLECTIVE INVESTIGATION OF YELLOW FEVER IN THE ISLAND OF CUBA.

BY D. T. LAINÉ, M.D.,
MAJOR AND BRIGADE SURGEON, U. S. V., HEADQUARTERS, DIVISION OF CUBA, HAVANA.

IN order to take advantage of the experience of Havana physicians on the subject of yellow fever, a set of ten questions was drawn up in this office and sent to the leading practitioners of the city. It is owing to the great kindness and courtesy of Drs. Santos Fernandez and Tomas Coronado, to whom are due sincere thanks, that so many replies were received. It will be observed that the questions were confined to points of practical interest. Thirty-five answers were received from physicians living in Havana, and two from Matanzas. All these were sent by men with large practices who live in the foci of infection of yellow fever and with sufficient experience in the treatment of this disease to give their personal opinions considerable weight.

We shall begin by analyzing in figures the opinions given, so that a reasonable criticism of the same can be found and we can come to a practical conclusion, if possible. This work was undertaken and accomplished by said physicians from a sense of courtesy and gratitude to Americans, in view of the special pains taken by them to study and modify the endemicity of this disease in Cuba, where it has wrought so much harm to its industries and inhabitants. Even the children, although natives, are none the less victims during their early age to the terrible scourge, which stands to-day as a barrier to immigration, for which so great a necessity exists in the island, from the mortality caused by war and from 400 years of criminal neglect of all sanitation.

1. What is, from your observation, the earliest period at which it is possible to make an accurate differential diagnosis of yellow fever, and on what do you base the diagnosis?

Three physicians claim that it is impossible to say precisely at what time the diagnosis can be made; seventeen claim that it can be made between the third and fourth days; fifteen between the first and third days. The diagnosis is based by the great majority on the symptoms which are common to yellow fever and which are present after the second day. Many draw attention to one or various symptoms; others give preference to the combination of symptoms if they are present in an individual who has recently arrived in the country, or to a native child who finds itself under the same conditions as a stranger.

The presence of mucine, the investigation of which has not been fully carried out, and albumin in the urine, which is apt to appear at the end of the second day, the characteristic remission which separates the first from the second period and which is noticeable between the second and fourth days of the disease, the icterus which appears on the third day, and the hemorrhages are the principal symptoms which carry conviction to the mind of the experienced practitioner as to the existence of yellow fever.

2. What do you consider the most pathognomonic symptoms of yellow fever?

Seventeen physicians are of the opinion that pathognomonic symptoms do not exist; eighteen accept not one symptom alone, but a number of them together as constituting pathognomism. The majority believe that the remission from the first period followed by the sudden elevation of temperature of the second period, in conjunction with albuminuria, icterus, and hemorrhages are the most typical symptoms of the disease. The physicians who accept a group of symptoms as constituting pathognomism express themselves as follows:

Remission from the first to the second period, albuminuria, icterus, hemorrhages; some add to the above black vomit and bloody evacuations (which should be put under the head of hemorrhagic symptoms), cephalalgia, rachialgia, congestion of the conjunctivæ, congestion of the face, which are nothing more than the phenomena which are proper to all infectious and acute febrile diseases, and which, although present in yellow fever are also common to many febrile conditions, and cannot be accepted as characteristic symptoms of the disease. The falling of the pulse, even if frequently observed, does not constitute, *per se*, a characteristic symptom of yellow fever, and it is more than likely dependent on one of its epiphenomena, biliary disturbances, which usually present themselves during the course of the fever, when the diagnosis has no longer the same relative value.

3. Given a case of chronic malarial fever, in which death occurs from an invasion of yellow fever, what will be the post-mortem appearance?

Twenty physicians express the opinion that the lesions of both diseases will be found; fifteen have never observed combinations of these two diseases and therefore can express no opinion. During the war and in the military hospitals it was not unusual to meet with soldiers suffering from yellow fever who came from the interior of the island suffering from acute malaria. In those rare cases in which a careful study of the disease was made, frequently both infections could be traced without one being able to positively state the distinctive features of either one.

4. Published statistics show a reduction in the mortality of yellow fever by the use of the Sternberg treatment. Why is it not more generally used?

Eighteen physicians claim that they do not use it because they have obtained the same results with other treatment; eight claim that the bichlorid of mercury is a source of danger: seven physicians express no opinion because they have not used it; two have used it and continue to do so.

It is an indisputable fact that since the work of Dr. Sternberg was published, the majority of the doctors in this island use the alkaline treatment, adding other drugs to it for which they have some personal predilection. A great many do not use the bichlorid, having an exaggerated fear of producing mercurialization, undoubtedly a troublesome complication, especially in those attacked with yellow fever.

5. What is your treatment of yellow fever?

Fifteen physicians use laxatives, disinfectants, alkalies and tonics; eight use the classic symptomatic medication; seven, absolute diet and light laxatives; two, eliminative medication, tonics and hydrotherapy; one, alkaline medication with bichlorid of mercury.

The great majority of opinions expressed in answer to this question, the most important of all, show the vacillation of the clinicians when dealing with an acute infection whose pathogenesis is unknown. Every physician is filled with enthusiasm when he obtains favorable results with a special plan of medication in this disease, but his disappointment has no limits when a new case in the same epidemic or another presents itself with possibly more benign symptoms and the patient succumbs when treated with the same medication which gave him such favorable results in the first case. On this account we see practitioners using all medication that is suggested for yellow fever and later on discarding them as they acquire the conviction of their inefficacy. As long as we have not a more complete knowledge of its pathogenesis we cannot hope for a rational or certain treatment. Those which are proposed will never be more than mere attempts to aid the patient in his defense against the germs and the unknown toxins which are destroying him. Statistics have shown until now the futility of all forms of curative treatments proposed for this disease. It is proper to know them all but to hope also that a new study, possibly that instituted by Sanarelli, may soon solve this interesting question.

5. What is the mortality in your own experience?

Fourteen physicians claim from 27 to 39 per cent.; thirteen give no statistics, and six claim that statistics are very variable. Yellow-fever statistics have no value unless they have been carefully gathered for a period of at least ten years. If we notice the great difference which exists, one giving 7 per cent. mortality and another 80 per cent., we cannot help but come to the following conclusions: Either these statistics, which represent such extreme limits, have been made from a limited number of patients in two distinct epidemics or else very benign or malignant groups of cases have been included in them.

The statistics given by the fourteen physicians give a mean average of 23 per cent., which is more in keeping with the mortality of the severe forms of infectious fevers. There is as great diversity of opinions in the rate of mortality given as in the treatment.

Now that the season approaches when there will be a recurrence of yellow fever and when, unfortunately, so many non-acclimated strangers will succumb, I should propose as an humanitarian means and as an important question for our country, that the sanitary officers place under the care of those physicians who claim a mortality of 7 or 8 per cent. two wards for the care of those cases. If such a reduction of mortality could be obtained yellow fever would lose much of its terrors.

7. What is your opinion of the fiebre de borras? In what does it differ from yellow fever?

Twenty physicians claim that it is the same as yellow fever; seven that it is a malarial fever; three have never met with it, and two declare that it is a symptom of various diseases.

The difference of opinion which is apparent in twelve of the physicians is proof that they are not yet fully convinced and are not willing to go against tradition, as not one of them gives conclusive proofs to show the nature of the so-called fiebre de borras, whose only true difference from true yellow fever is the fact that it appears in the natives.

The notable works of Dr. John Guiteras, late Professor of Pathology in the University of Pennsylvania, on the epidemology of yellow fever, and those of Dr. Mudan of Matanzas, and others which have been made here in Havana during the past three years, show experimentally that "fiebre de borras" is without question yellow fever.

We shall only bring forward one argument. If

fiebre de borras was by nature paludic, why is it not observed in Europe or in any other country where malaria exists? Is it reasonable to suppose that this is but a rare privilege conceded to Cuba and other foci of yellow fever to have this special form of malaria?

It is only necessary to carefully observe a few cases of fiebre de borras for the most exacting clinician to become convinced of its yellow-fever origin. The majority of the physicians concede the identity of this fever with yellow fever.

8. What do you understand by acclimatization fever?

Twenty-three physicians affirm that it is a mild form of yellow fever. Ten do not know what acclimatization fever is; two refuse to believe it yellow fever.

Physicians in Cuba who have studied the fevers of the island have not without good reason given the name of acclimatization fever to that fever, different from other well-known forms, and which always makes its appearance in times of yellow-fever epidemics. Acclimatization fever is the mildest form of yellow fever. If its similarity to catarrhal fevers or to simple fevers caused by gastric disturbances or to others of simple nature is held up as proof of its not being a form of yellow fever, no importance should be attached to the fact. Learned clinicians of repute affirm that the so-called acclimatization fever confers immunity to a later and complete attack of yellow fever. This fact alone confirms what a respectable majority of the physicians interrogated recognize.

9. What do you consider the most dangerous part of the city of Havana, in relation to yellow fever?

Twenty-three physicians are of the opinion that the shores of the bay and the districts in the vicinity of the wharves constitute the most infected parts: seven, that these are to be found in the Military Hospitals, and buildings contaminated by having sheltered previous cases. Six state that the entire city of Havana is a permanent focus of contagion.

The whole thirty-five replies confirm the result of observations extending over a long period of time. The majority believe that the shores of the bay and districts adjoining the wharves are the most dangerous. In truth, in these places contagion is more active for two powerful reasons that tend to bring it about: First, the continuous crowding of foreigners, it being the commercial part and more densely populated by newly arrived Peninsular Spaniards, who through long-established habit come to live in the warehouses and establishments of their relatives and friends. These newly arrived immigrants constitute the most favorable means of cultivation of germs that this filthy and badly ventilated part of the town maintains in a latent state. Second, the proximity of the fortresses, barracks and arsenal that forced the Spanish soldiers to remain in their vicinity rather than in other parts of the city, and furthermore, the sending yearly of new Spanish soldiers who have always been in Cuba the sustainers of yellow fever and the propagators of its epidemics, from the fact of its contagion being denied (or not believed in) and there never having been measures of isolation and disinfection adopted. The fact of several officers dying successively in a building or quarters in the barracks of La Fuerza and other places has been constantly repeated up to the month of December, 1898, without it occurring to any one to scientifically disinfect those quarters after the deaths occurred and much less to isolate the sick. Hotels and boarding-houses of these districts, with Spanish officers as inmates, were so many more centers of contagion. To the Military Hospitals and infected buildings there must be added the Casas de Salud, (private infirmaries) of this capital, which, although their owners try to hide it, give and have always given a terrible contingent of yellow-fever cases. In these houses isolation is a myth; in the room of a yellow-fever patient there enter at all hours, and retire without disinfecting themselves, friends and acquaintances who unconsciously disseminate through the whole city the contagion of the yellow epidemic.

10. What precautions would you recommend for unacclimated people?

Thirteen physicians recommend observance of the general laws of health; nine, the running away from the contagion; seven, living beyond the foci of yellow-fever infection; three, the return of foreigners to their native countries. Two state that it is not possible to suggest a precaution. One recommends preventive inoculations. Here we come in contact with the difficulties arising from lack of knowledge. If we do not know the pathogenesis of the disease, how can we adopt precautionary or preventive measures? All the measures recommended are good, but they are without any practical basis. What does the rigorous observance of health-rules and even the flight from contagion amount to, of a non-vaccinated person in the midst of an epidemic of smallpox? The same happens with yellow fever, the specific germ of which, unfortunately, has not been sufficiently experimented with to warrant the certainty of its identification.

To fly from the contagion and live beyond the yellow-fever centers, is an impracticable measure which many foreigners are debarred from carrying into effect. The return of foreigners to their native country (which would entail a financial disaster to this country) and which three esteemed physicians

recommend, would simply prevent those foreigners, so returning, from dying here and nothing else. In corroboration, it is well to bear in mind the case of the unfortunate American engineer, Waring, who, although probably living under the most excellent hygienic conditions, could not escape contagion and, returning to his native country, fell a victim to the yellow fever which he had contracted here. And, on the other hand, the children of the island under ten years of age, not being immunes through a previous attack, would have to be banished therefrom.

It is not to those in health but to the sick that efforts must be directed to prevent contagion of yellow fever, establishing the strictest isolation, the same as if smallpox, the plague, dysentery or other contagious disease were being treated; to prevent its progagation so that the germs may die out through lack of material to feed upon. In this manner alone will it be possible to banish yellow fever from infested Havana, and Cuban soil throughout the island, brought about by the effect of war.

Modern medical science may well be proud of its preventive treatment of contagious diseases, which heretofore decimated whole cities, spreading desolation, terror, and ruin. Yellow fever belongs to this class, and its prevention is not a Titanic work nor one to be left for some future time. It belongs by right to men of the epoch of Pasteur, aided by some legislation that recognizes that public health is the most important of all things.

CRURAL THROMBOSIS FOLLOWING ASEPTIC CELIOTOMY.[1]

BY HENRY C. COE, M.D.,
OF NEW YORK.

AMONG the later complications of abdominal section for disease of the pelvic organs there is none that causes more annoyance to the surgeon and disappointment to the patient than the one which will be briefly discussed in this paper. Occurring, as it often does, in simple cases in which a rapid recovery had been confidently expected, and at the end of the first, or beginning of the second week, when all anxiety regarding the condition of the patient has been dismissed, its appearance is as unexpected as it is unwelcome. One whose surgical training has rendered him skeptical regarding the development of post-operative thrombosis from general causes, at once thinks of local sepsis, his suspicions being strengthened by the detection of an induration in the broad ligament, or at the site of the stump, on the affected side, and he begins to review his technic carefully in search of some broken link in the chain. If other sources of infection can be excluded he is apt to infer that his catgut was faulty, since it is well known that the center of the coarser sizes may be imperfectly sterilized and may not manifest its dangerous qualities until sufficient time has elapsed to allow the aseptic peripheral portion to become dissolved. Even though the bacteriological examination of the suspected piece is negative, it is impossible for him to dismiss the notion that there is a septic element in the case. Since there is, fortunately, no opportunity for post-mortem investigation, he is obliged to base his opinion entirely on clinical evidence, which is mainly negative.

That there is a general disposition to regard crural thrombosis following abdominal section as being purely of septic origin, and practically identical with the milder grade of puerperal phlegmasia dolens, once so familiar to obstetricians, is shown in the brief allusions to this complication in many textbooks and monographs. Kelly and Greig Smith, however, representing the most advanced teaching in abdominal surgery, carefully avoid using the word sepsis in this connection. The latter, in the last edition of his well-known work, devotes only eight lines to the subject of "edema of the legs," concluding with this statement: "Most cases could doubtless be explained by some traumatism or compression of a venous trunk in the pelvis by forceps or ligature; a few might arise from pelvic cellulitis or angioleucitis."

This explanation is plausible, but far from convincing, since it fails to account for the comparatively rare occurrence of thrombophlebitis after total extirpation in bad pus cases, in hysterectomy, in myomectomy, and especially in puerperal hysterectomy, where there is always marked dilatation of the vessels of the broad ligaments and mass-ligatures and clamps are so feely employed. Certainly if traumatism played an important part, the use of the angiotribe would seem to be especially favorable to the development of this condition, which is not the case.

As this paper is essentially clinical, I shall not burden you with a consideration of elementary facts regarding the nature and causation of thrombosis and phlebitis or review the various theories of Virchow, Cornil, *et al.* The subject is quite an old one, and reference to the English journals as far back as the early fifties shows that puerperal phlegmasia had been carefully studied at that time. Opposing papers by Lee, MacKenzie, and Tilbury Fox[1] furnish interesting reading from a historical, if not from a scientific, standpoint. Lee and Fox regarded phlegmasia as a local, MacKenzie as a constitutional, affection.

[1] Read at the twenty-fourth annual meeting of the American Gynecological Society, held at Philadelphia, May 23, 24, and 25, 1899.

[1] *British and Foreign Medico-Chirurgical Review*, p. 55, 1854; *Medical Times and Gazette*, vol. ii, p. 46, 1862.

H. Lee, in an earlier paper,[1] had already opposed the view of extension of a septic clot from the uterus, and affirmed his belief that crural phlegmasia was the local expression of a blood infection. This seems to have been the general opinion at this time, as it was reaffirmed by J. Y. Simpson.[2] Vaquez's monograph[3] is a distinct addition to the literature of this subject, and contains many suggestive sentences, which I would like to quote if time permitted. He takes issue with Virchow, agreeing with Widal[4] that phlegmasia is due to infection, even in the mild cases, which are attended with slight chills and moderate elevation of temperature. He is somewhat confusing, since in another place he refers to "aseptic" phlebitis following ligation or other injury to a vein, and states that an aseptic thrombus may subsequently become infected. The micro-organisms found in the thrombus, he says, may be identical with those at the original focus of infection, or they may be a different variety, invading the vein from without by way of the vasa vasorum. Thrombosis, he concludes, is not a simple clotting of blood, but is always secondary to phlebitis. It is interesting to note that he regards it as a rare complication of simple ovariotomy.

Of all the papers which I have read Wyder's gives the most information regarding thrombosis following aseptic celiotomy. His article on "Embolie der Lungenarterien in der geburtshilflich-gynäkologischen Praxis"[5] is based on twelve cases with eight deaths, which were carefully investigated post-mortem. Unfortunately no bacteriological examinations were recorded. As the author says, they furnish a startling commentary on the unavoidable dangers of abdominal section. The gynecological cases are so interesting that I venture to insert brief abstracts of them.

CASE I.—Virgin, aged forty years, with old varicosities and edema of both legs. Interstitial fibroid the size of the fist. Castration. Operation simple, and afebrile convalescence up to the fifth day, when the patient complained of sharp pains in the left foot. She expired suddenly on the same night. Autopsy showed partly decolorized thrombus in the left saphenous, extending into the femoral. Pelvic veins normal. Emboli in the main branches of both pulmonary arteries.

CASE II.—Virgin, aged forty-four years. Castration for fibroid the size of a child's head. Operation simple. Convalescence normal until the fourteenth day, when the heart action became rapid and irregular, and she died in a few minutes. At the autopsy the veins in both stumps were thrombotic, and the main branches of the pulmonary arteries were plugged with fresh emboli. Marked dilatation of the left ventricle.

CASE III.—Virgin, aged thirty-four years. Supravaginal amputation of the uterus for multiple fibroids, with extraperitoneal treatment of the stump, the operation being uncomplicated. Afebrile recovery until the eight day, when she expired with symptoms of pulmonary asphyxia. The left hypogastric vein contained a thrombus, and both pulmonary arteries were plugged.

CASE IV.—Primipara, aged thirty-eight years. Removal of the adnexa and ventrofixation. No symptoms until the eleventh day, when the patient was feeling quite well. She was suddenly attacked with dyspnea and died. Autopsy unsatisfactory, as the source of the emboli could not be discovered.

CASE V.—Multipara, aged thirty-nine years. Removal of intraligamentary ovarian cystoma of the left side, also the right tube and ovary. No symptoms until the tenth day, when the patient complained of feeling bad, and died in ten minutes. Numerous thrombi were found in the veins on the left side of the pelvis, extending into the left hypogastric. Emboli in both pulmonaries.

CASE VI.—Explorative section for carcinoma of the ovaries and peritoneum. Normal convalescence until the seventh day, when sudden death occurred with cyanosis. Thrombus (presumably old) in the vena cava inferior, with pulmonary emboli.

CASE VII.—Virgin, aged twenty-seven years, in robust health. Ventrofixation after removal of the left tube and ovary. Convalescence entirely normal until the seventh day, when she had an attack of dyspnea with rapid pulse, from which she rallied. Two other attacks occurred during the night, attended by severe pain under the left scapula, the third terminating fatally. The left pulmonary artery contained a recent embolus, but its origin could not be found. The writer believes that the accident was directly due to the operation, and that a thrombus must have developed in the veins of the stump, which had been completely dislodged, leaving no trace.

In summarizing Wyder states his belief that thrombosis in both the pelvic and crural veins is not uncommon after celiotomy, but that the thrombi are generally absorbed if they do not become infected. They are by no means confined to complicated operations, as shown by his cases. In general, pulmonary emboli are due to thrombi in the pelvic rather than in the crural veins, and give rise to no symptoms until they have extended to the vena cava. They may be present before operation, hence great care should be observed in operating upon patients with evidences of venous obstruction, especially if the heart action is weak, since even perfect asepsis does not guarantee recovery.

Mahler,[1] in an article on the same subject, reports fourteen fatal cases of pulmonary embolism occurring in the Dresden clinic between 1884 and 1894, six after gynecological operations. In every case brown atrophy or fatty degeneration of the heart was also found (as in the nine cases reported by Hoffmeier). He calls attention to the fact that when a large neoplasm is removed the intra-abdominal pressure sinks and the pelvic veins become dilated. Three varieties of thrombus formation are to be distinguished, *viz.*, the thrombus may extend from the uterus

or its immediate vicinity into the pelvic veins; it may originate in the crural vein and extend upward into the iliac; it may form in the dilated veins of the broad ligaments, which are flabby, thin-walled, and cannot contract, so that the circulation is retarded. Moreover, the veins may be compressed by plastic exudate. The surface left after the enucleation of a fibromyoma is analogous to the placental site. Old thrombi may be present at the time of operation. Schwanz reports two fatal cases of embolism due to the detachment of such thrombi, and Dohrn[1] one in a case of fibroid before operation. (I recall a similar case at the Woman's Hospital in the service of Dr. Thomas.) Such thrombi are not infrequently present in the veins of the thickened broad ligament in connection with inflammatory disease of the adnexa or twisted pedicles, and extend into the pampiniform plexus after operation. After hysterectomy thrombi may form in these plexuses and in the uterovaginal veins on both sides. The capillary system of the broad ligament is such that the collateral circulation is established slowly.

In conclusion Mahler also calls attention to the more serious significance of intrapelvic as compared with crural thrombosis, since in the crural veins the thrombi tend to become organized, while in the pelvic veins, which are without valves, the clot may extend up into the iliacs, whence emboli may be carried directly to the lungs. In regard to crural thrombosis he adds the caution that the absence of edema is no indication that serious trouble is not present.

A recent contribution to the subject of thrombosis and embolism by Singer[2] deals more particularly with peculiarities of the pulse-curve, especially in fatal cases. Although his conclusions are based on observation of the phenomena attending puerperal thrombosis, they are applicable to some extent to post-operative cases. He distinguishes simple and inflammatory thrombi; the latter may be due purely to gonococcus infection, as shown by bacteriological examination, in which case the condition is not true puerperal phlegmasia. Singer evidently does not subscribe to the view that all thrombi are of septic origin.

It must be confessed that a careful review of the literature has failed to establish the etiology of post-operative thrombosis, especially with regard to the important question of septic infection.

For information on this obscure subject I naturally sought the fountain-head, and addressed a letter to Professor William H. Welch, who, in the kind and helpful spirit which always marks his attitude toward his younger brethren, replied at considerable length to my queries. I take the liberty of quoting several sentences from his letter:

Femoral thrombosis or phlebitis occurring under the conditions which you describe is a very interesting subject, but I do not think that the underlying causation is understood. I am familiar with this class of cases, as several similar instances have been observed here, particularly after gynecological operations, but also after other surgical operations on the abdomen, as for the radical cure of hernia, and, indeed, after surgical operations in general. In most cases there was nothing to raise suspicion of any septic or infective condition before the onset of the thrombosis, and then nothing but the thrombosis. In at least one instance the thrombosis involved the veins of an upper extremity. I do not know how well founded may be the impression which I have seen expressed that this complication is more common now than formerly.

Of late years some writers, particularly of the French school (Cornil, Widal, Vaquez), consider practically all venous thromboses, including those formerly called marantic, as infective, and it is true that bacteria have often been detected in these thrombi. Still, there are not a few negative results in examining the same class of cases, and I think that it is going altogether too far to generalize on the observations thus far collected and to assume that all these plugs are due to infection. Some have thought that the frequent onset with chills, elevated temperature, and rapid pulse indicated positive infection; but while, of course, suggestive of such an interpretation, I do not think that these symptoms are conclusive upon this point.

We have been examining bacteriologically this winter all the thromboses found at autopsy, and while several, perhaps the majority, have contained bacteria, oftenest streptococci, others have been sterile, so that I am not convinced of the infective origin of all such cases as you describe. Take the thromboses complicating chlorosis; these are often severe, with chills, high temperature, etc., and still thus far (with one very unconvincing exception) their bacteriological examination has been negative.

But I do not think that we can at present exclude infection in all these cases as the cause, and if we reject this explanation we should be quite at a loss for any other explanation. I am, therefore, inclined to the hypothesis that your cases and similar ones are due to infection, but at present this is only a hypothesis, and its foundation is mainly the difficulty of assigning any other probable cause. What is needed is an anatomical and bacteriological examination of the thrombi in these cases, and as the termination is usually favorable, the opportunities for such examinations are necessarily rare.

This is all very unsatisfactory I know, but the whole field is one which needs cultivating before any definite conclusions are warranted."[1]

The following cases occurred in my practice between May, 1898, and May, 1899:

Case I.—(Private.) Multipara, aged thirty-five years, with excellent general health, but with a history of recurrent attacks of peritonitis and constant abdominal pains. Diagnosis: Laceration of the pelvic floor, retroflexion with adhesions, diseased adnexa. Operation May 19,

[1] *Zeitschift fur Geb. u. Gyn.*, Band xi.
[2] *Archiv für Gynäkologie*, Band lvi, p. 218, 1898.

[1] Dr. Welch's article on thrombosis, in the recently published volume of Allbutt's "System of Medicine," contains an interesting summary of existing views on this subject with copious references.

1898. Divulsion and curettement, colpoperineorrhaphy, followed by removal of both adnexa and the adherent and diseased appendix, and internal shortening of the round ligaments. Adhesions slight, and no raw surfaces left within the pelvis. Separate ligation of the ovarian arteries, excision of the tubes, and suture of the broad ligaments in the usual manner, so that no stumps were left. Catgut used throughout. Convalescence normal, the highest temperature being 100.2° F. on the first day after operation. The patient began to complain of pain along the course of the left femoral vein at the middle of the second week. Well-marked induration was felt in the usual locality just below the groin, with slight edema of the foot and ankle. Pulse below 100, and temperature 99.5° to 100° F. No constitutional disturbance. Pelvic examination negative. Primary union of the wound.

The patient was kept absolutely quiet, but during my absence from the city for a day (on the twenty-fourth day) she insisted on being transferred to her home, which was only a short distance from the hospital, where she remained in bed for two weeks longer. Stiffness and edema persisted for two or three months, so that she was obliged to wear an elastic bandage, but she eventually made a perfect recovery, and has since led an active life, taking long bicycle rides, etc.

CASE II.—(Private.) Multipara, in good general health, aged thirty years. Sterile after six years of married life, suffering from severe dysmenorrhea and persistent pain in the right ovarian and appendical regions. Diagnosis: Anteflexion with stenosis, disease of the right ovary and tube, and possibly of the appendix. Operation July 1, 1898. After divulsion and curettement the abdomen was opened and the right ovary and tube were removed, with the thickened and adherent appendix. Ligation with catgut, no stump being left. Left ovary and tube entirely normal. During the night following the operation (the weather being intensely hot) her temperature rose to 103° F., but without acceleration of the pulse or indications of local trouble. During the week which followed the thermometer was seldom below 90° F. in her bedroom, and she suffered greatly from the heat in spite of ice-bags and cold sponging. Her temperature was irregular, ranging from 101° to 102.5°, but without any evidence of sepsis, so that no alarm was felt with regard to her ultimate recovery. On the fifth day she began to complain of pain in the left leg; a day or two later tenderness in the left groin on deep pressure was noted. By vaginal palpation a small, sensitive induration was detected at the base of the left broad ligament. Her temperature declined steadily after the first week, and soon dropped to 100° F., while there was at no time any marked acceleration of the pulse (it was seldom above 100) or constitutional symptoms.

The thrombophlebitis was quite obstinate, pain persisting for two weeks, while the edema was well marked. The pelvic induration could not be felt after the second week. Primary union of wound. She left for the country five weeks after the operation, wearing an elastic bandage, but did not make a complete recovery until fall, when she reported in excellent condition. I heard through her physician, six months after the operation, that she was entirely relieved of her former pains.

I have never been able to assign a satisfactory explanation for the sudden elevation of temperature. Insolation was suggested as a possible cause. Fever developed too early for local sepsis, and was too persistent for ordinary traumatic reaction. The patient was exceedingly nervous and restless, but I have never admitted "nervousness" as a cause of fever after surgical operations.

CASE III.—(Private.) Multipara, aged thirty-two years; general health good. Pressure symptoms, dysmenorrhea and menorrhagia, and more or less constant pain in the right inguinal region. Diagnosis: Small ovarian cyst. Operation November 3, 1898. Curettement, followed by removal of a cystoma of the left ovary, the size of an orange, non-adherent. Right ovary and tube normal. Catgut ligatures, and no stump. Appendix, the size of the thumb, removed and found to contain concretions, with marked thickening of its walls. Convalescence afebrile until the tenth day, when the patient began to complain of pain in the left leg. The temperature rose to 100° F., and fluctuated between 100° and 101.5° F. during the next ten days, the pulse seldom exceeding 100. Pain and induration along the left crural vein, but at no time was there any edema of the foot and ankle, merely a slight increase in the measurement at the calf. Vaginal examination negative. Constitutional disturbance limited to headache, coated tongue, diarrhea, and sleeplessness. Primary union of wound. The family physician came to the conclusion that the patient had developed a mild case of typhoid, which I doubted. The temperature became normal after three weeks, and she went home during the fifth, wearing a bandage. She remained in bed for a fortnight longer, and called to see me two months after the operation, feeling quite well, with the exception of some stiffness of the leg, which prevented her from walking more than two or three blocks at a time. This soon disappeared, and she has since been in good condition.

CASE IV.—(Hospital.) Virgin, aged forty years, a dressmaker, who had always enjoyed good health. She had a large ovarian cyst, which had undoubtedly existed for eighteen years (!), without giving rise to marked symptoms, until within the past year, when it began to grow rapidly. Operation March 4, 1899. Dermoid cyst, springing from the left ovary, entirely without adhesions, although it filled the abdomen. Right ovary and tube normal. Catgut ligatures, with suture of the broad ligament in the usual manner. Temperature reached 100° F. only once, on the third day; pulse never above 90. Toward the end of the second week she began to complain of pain along the course of the left femoral vein. Moderate edema of the foot and ankle. Vaginal examination negative. No constitutional disturbance. Primary union of wound. The symptoms rapidly subsided, and the patient insisted on leaving on the twenty-sixth day against advice. She remained quiet for two or three weeks, and made a perfect recovery. I saw her on May 15th, when she had no remains of the trouble, except slight stiffness in the affected limb, which did not interfere with locomotion.

CASE V.—(Private.) Multipara, aged forty-five years, strong and well-nourished. Had suffered for several months with menorrhagia, pain in the lower abdomen, and pressure symptoms. A fluctuating tumor the size of a grape-fruit was felt to the right of and anterior to the uterus, the organ being enlarged to three or four times its normal size. Diagnosis: Ovarian cyst.

Operation March 23, 1899. Divulsion and curettement, a small fibromyxomatous polypus and a quantity of fungosities being removed. Non-adherent cystoma removed from the right side and a commencing cystoma of the left ovary. No evidence of fibroid growths. Catgut ligatures, and no stumps left.

Convalescence entirely afebrile until tenth day, when,

after a slight chill, the temperature rose to 100° F., and the patient began to have pain at the origin of the left saphenous vein. The pain was more severe than in either of the previous cases, and was persistent, being only relieved by the constant use of an ice-bag (which I have found is the best local application in this condition), but the temperature only once reached 102.5° F. in the evening, dropping to 99° F. in the morning. The pulse at no time exceeded 100, the average rate being 80, even when the temperature was elevated. Marked induration along the saphenous vein, with considerable edema of the thigh, but none below the knee. Mild constitutional disturbance. Vaginal examination showed a distinct, painful induration at the site of the left stump, which could be traced outward to the pelvic wall. This disappeared in a few days with the use of hot douches (as in Case II.), while the crural phlegmasia was at its height. Convalescence was tedious, but the patient's general condition was excellent; she took plenty of nourishment, slept well, and preserved her usual equanimity. The temperature declined to normal at the end of the fourth week, when she was allowed to move to the lounge. As the pain returned (without rise of temperature) she was kept in bed for another week, and was not able to walk about her room until six weeks had elapsed after the operation. She went to church a week later, and is now (exactly two months after the operation) in excellent condition.

Just after writing the foregoing my attention was called to a sixth case, which seems to belong under this category.

CASE VI.—(Private.) Primipara, aged twenty-one years, a well-nourished German, whom I saw for the first time April 6, 1899. She was delivered at term three days before. Labor had proceeded normally for twelve hours, when the head was arrested at the perineum, the pains becoming inefficient. The attending physician administered two drams of ergot, soon after which the child was suddenly expelled with a violent pain; a half minute later a second contraction occurred, completely inverting the uterus. The placenta was implanted centrally at the fundus, the cord being unusually short. The doctor peeled it off and attempted to replace the uterus, which was impossible on account of the firm contraction of the ring. The hemorrhage was profuse, the patient collapsed, became pulseless, and was only kept alive by saline enemata and hypodermatic stimulation. Twelve hours later her pulse was 180, and the following day it remained at 150, and was quite feeble. Forty-eight hours after the accident an attempt at reduction was made under anesthesia, but she again collapsed, so that the manipulation was continued for only a few minutes. She was transferred to my service in the General Memorial Hospital seventy-two hours after the accident, having a pulse of 130 and a temperature of 101° F., exsanguinated, with unmistakable evidences of sepsis. Under light anesthesia the diagnosis of complete inversion was confirmed, but no attempt was made at reduction on account of the necrotic condition of the endometrium and the patient's extreme weakness. Decomposed membranes and bits of placenta were removed, douches of pure peroxid of hydrogen and saline solution were given and the vagina was tamponed.

During the next two weeks the temperature ranged from 99° to 101.6° F., the pulse varying from 90 to 120. Douches of peroxid and saturated solution of boric acid were used, at first every six hours, later twice daily. The patient improved rapidly, her recovery being retarded by several ugly abscesses on the arms and legs (a legacy of the accoucheur). She sat up on the twenty-third day, and menstruated normally two days later without discomfort, normal involution having occurred. On the thirty-second day after entering the hospital (the thirty-fifth since the accident) she was in a good condition for operation.

Under anesthesia it was at once evident that reduction could not be effected by ordinary manipulation. Although the uterus was small (about the size of a Bartlett pear), the contraction ring was unusually tight. The abdomen was opened, and with the able assistance of Dr. Jarman, after half an hour of hard work, the ring was stretched with the fingers and a Wathen's dilator (the ends of which were guarded with rubber tubing), and we succeeded in replacing the inverted organ. The tubes, ovaries and broad ligaments were perfectly normal, and there was no evidence of any obstruction to the circulation. As the round ligaments were greatly elongated, it was deemed advisable to shorten them by Mann's method. No reaction after the operation. Temperature on the following day was 99.4° F., and after the fourth day 98° to 99° F., the pulse ranging from 80 to 90. Convalescence entirely normal up to the ninth day, when examination of the wound showed primary union. The same evening the temperature rose to 100.2° F., the pulse being 90, and the patient complained of pain in the left groin and inner aspect of the thigh. It appeared later that she had felt slight pain on the previous day, but had not alluded to it. Examination per vaginam on the following day revealed a tender cord, which could be traced from the side of the uterus along the base of the broad ligament to the pelvic wall, where it was evidently continuous with an induration at the beginning of the saphenous vein. Uterus small, in normal position, and insensitive. No vaginal discharge; no edema of the limb. The evening temperature was 101° F., the pulse 92. No constitutional symptoms. On the eleventh day the temperature ranged from 100.4° to 102.2°, the pulse being 112. Pain moderate, and slight edema of the foot noted. On the twelfth day temperature 100.4 to 102° F., pulse 106 to 112. Treatment: Hot vaginal douches, ice-bag, elevation of the limb, strychnin and quinin. Patient taking plenty of nourishment and presented no septic symptoms.

On the following day her temperature fell to 99° F., the pain and edema rapidly disappeared, and she was discharged at her urgent request, in the fourth week, without any trace of local trouble. The pelvic organs were entirely normal. Two weeks later she was in excellent condition.

I have few comments to add to these clinical notes. A rigid revision of the technic, both by my associate, Dr. George W. Jarman, and myself, failed to reveal any loophole by which infection could have crept in. Dr. Jarman himself assisted me in four of the private operations and personally attended to the sterilization of the instruments and field of operation. The nurse was not allowed to touch anything that came in contact with the wound. According to our usual custom, after thorough sterilization of the hands by the method employed at the Johns Hopkins Hospital, rubber gloves were worn, which were removed immediately before the operation, when the hands were again washed in alcohol, bichlorid 1:1000, and saline solution. Neither of us had recently attended a septic case. The catgut, prepared by Levens, was regarded as above suspicion,

and the tubes were sterilized with the instruments. In short, as the cases were important ones, every precaution was taken to insure a perfect result. The disappointment at the failures was therefore so much the keener.

Certain negative points should be emphasized. No foci of infection were discovered during the operation. Mass ligatures were not used, no stumps were left at the uterine cornua, and no raw surfaces remained within the pelvis, yet in three cases there was evidently thrombophlebitis of the veins in the broad ligament of the affected side, which, presumably, was continuous with the process in the crural vein. Curiously enough, in Case II. there had been no lesion of the tissues on the left side, as the tube and ovary were normal. The pelvic indurations disappeared within a week, while the crural thrombosis was at its height, leaving absolutely no traces, such as often persist for months in the case of inflammatory exudates surrounding silk ligatures and infected stumps. The patients were all in excellent general condition before and after the operation, with no evidence of circulatory disturbance, so that the theory of marantic thrombosis is untenable. No traces of varicosities of the veins of the extremities or of those within the pelvis were noted. The bowels were moved daily after the third day in each instance. In none was there any disturbance of the stomach, or any symptoms causing anxiety with regard to the ultimate recovery of the patient. Pain in the affected limb was the most marked symptom, and in all but one case it was sufficient to constitute a true phlegmasia dolens. Induration was present in all, but the edema was moderate, localized, and transient, leading to the inference that either the thrombi were parietal, or that the collateral circulation was free. Recovery was rapid as compared with ordinary cases, even though the mistake was made of allowing the patients to leave their beds too soon. In but one instance did a chill occur, and in only two was there the acceleration of the pulse, on which Singer and others lay much stress. In short, the clinical histories throw little or no light upon the etiology of the condition. Certainly the occurrence of six cases of this character within a year in the comparatively limited experience of a single operator must be regarded as unusual, if not unique.

It is interesting to note that the appendix was removed in three cases. Attention has been called by Welch to the fact that crural thrombosis has been noted in several instances as a complication of this operation.

In this connection I may be permitted to refer briefly to a case of crural thrombosis following trachelorrhaphy—a rare complication after this simple operation, considering the number of times that it has been performed and the septic infection (sometimes fatal) which used to attend it in the early preaseptic days. Why it should be so infrequent I do not know, in fact, I have never met with any allusion to it in the voluminous literature of Emmet's operation.

The patient (private) was a delicate subject, aged twenty five years, whose only labor had been rather severe, terminated by forceps. Bilateral laceration of the cervix, with fixation of the uterus, due to a large cicatrix extending to the base of the left broad ligament; laceration of the pelvic floor. Operation January 6, 1898. Strict aseptic precautions were observed, as in vaginal hysterectomy. Curettement, bilateral denudation of the cervix, the cicatrix on the left side being dissected out. Chromicized-gut sutures. Hegar's colpoperineorrhaphy, with a continuous suture of chromicized gut within the vagina and a few external sutures of silkworm gut. Convalescence afebrile, and the patient was kept absolutely quiet for two weeks. Toward the end of the second week she complained of some stiffness in the left leg, but had no rise of temperature above 99.5° F. A well-marked thrombophlebitis developed, with considerable pain and edema. There was tenderness on palpation in the left lateral fornix, but no induration could be left. Primary union of perineal and vaginal wounds. The patient suffered from pain and edema for several weeks after the operation, and could not walk without a bandage. Examination of the cervix at the end of a month showed excellent union, and nothing abnormal could be detected in the pelvis. It was at least six months before she experienced the benefit of the operation, and her example naturally deterred some of her friends from running the risk of a similar experience at my hands.

In the absence of any evidence of sepsis, and considering the anemic condition of the patient, I was inclined to believe that this was possibly a case of so-called anemic thrombosis, with which the operation had nothing directly to do. This view, however, is open to criticism.

The question of most practical interest in connection with this subject is that of prophylaxis. Is it possible to foresee and to prevent thrombosis after celiotomy? Judging from the cases which I have reported, we are not yet in a position to give an affirmative reply. Wyder and Mahler advise not to operate upon patients with weak hearts, varicosities, and edema of the lower limbs. But all surgeons operate under these conditions, yet the number of cases of thrombosis and embolism are insignificant considering the number of operations. Wyder's inference that the frequency of this complication must increase with the constant increase in surgical activity is hardly borne out by the facts. Certainly the mortality after celiotomy in the foremost foreign and American clinics has steadily decreased with the perfection of modern aseptic technic. Improved methods of operating

and greater experience and manual dexterity have reduced the actual period of anesthesia, and with it the number of deaths from shock, hemorrhage, and visceral complications.

Sepsis is, and always will be, the one enemy which we have to fear. When we have succeeded in banishing it, at least from without, will thrombophlebitis be also eliminated in cases which were aseptic before operation?

The diagnosis of thrombosis confined to the pelvic veins, as shown by Wyder's cases, is practically impossible; but when combined with the crural variety (as in three of my own cases) it may be inferred from the presence of an induration extending along the broad ligament of the affected side. The recognition of crural phlegmasia after it is fully developed is so easy that even a tyro would not overlook it; but it has been affirmed that an expert should recognize the latent symptoms which appear in what Vaquez calls the "pre-obliterating" stage.[1] Singer,[2] who has devoted considerable attention to a study of the pulse, claims that it is always more rapid than usual from the outset (that is, after the disturbance attending the operation should have subsided), and that after the seventh day the curve rises sharply, reaches its acme on the ninth day, when the local signs of obstruction appear, there being a direct relation between the pulse and the gradual development of thrombosis, with the consequent increased resistance to the circulation. In a typical case the curve rises rapidly, while the temperature is still normal, and remains high after the latter drops. This peculiarity of the pulse (designated as *staffelförmiger* or *Treppenpuls*) is regarded by all recent observers as the most important, in fact, the only early indication of beginning thrombosis. It was most characteristic in the fatal cases of pulmonary embolism, so that its persistence and accentuation are regarded as somewhat ominous. Since it was not marked in my cases I infer that they belong to a different type from those on which Singer based his conclusions—in fact, the phenomenon seems to be most marked in pueperal phlegmasia. It would seem to point to a septic condition, in the diagnosis of which it is well known that the pulse is often of more value than the temperature.

So far as my own experience has gone, a slight elevation of temperature (99.5° or 100° F.) is most apt to attract the attention of the ordinary observer, and, in the absence of evidences of trouble in the wound or within the pelvis, to lead to the suspicion that phlebitis is developing; but careful questioning of the patient will often elicit the information that slight stiffness of the leg was noted before any other symptoms appeared.

The pain is often entirely out of proportion to the extent of the lesion. I do not know that it has ever been satisfactorily explained, unless we accept Simpson's view that it is caused by stretching of the walls of the vessel. The early notion that it was due to an accompanying peripheral neuritis he positively rejected, though it is now held by careful observers.

Edema is nearly always present, though it may be so slight as to be appreciated only on careful measurements of both limbs. In this respect my cases presented a marked contrast to the phlegmasia attending puerperal and post-operative septicemia.

The prognosis in the class of cases which I have described is favorable as regards both a rapid recovery and complete disappearance of the local trouble; but the experience of the German surgeons whom I have quoted serves to emphasize in quite a startling way the fact that thrombosis following aseptic celiotomy is a complication which cannot be regarded with indifference. The sudden onset of pulmonary embolism in patients whose condition had not previously caused the slightest anxiety furnishes a forcible commentary on the uncertainty of the prognosis, as well as the absolute helplessness of the surgeon.

In regard to treatment it cannot be said that the usual local applications or general medication influence the course of the affection, either by limiting the extent of the thrombus, or by hastening its resolution. Absolute rest in the recumbent posture without manipulation of the affected limb, although irksome to the patient, is the most important point. We are apt to yield to her importunities, and to allow her to sit up too soon. The disappearance of the local pain, induration, and edema, and the continuance of a normal temperature for several days are usually regarded as indicative of complete recovery; but as long as the pulse remains at 90 or 100 it is well to err on the safe side, and to keep the patient in bed a few days longer. Singer even insists that the recumbent posture should be maintained for at least three weeks after the pulse has become normal. Although this caution may seem to be extreme, it will at least prevent a relapse, with the consequent annoyance to the patient, even though the risk of pulmonary embolism may be so slight as to be disregarded.

[2] *Loc. cit.*

The Population of Puerto Rico Increasing.—At San Juan during the month of May, 1899, there were sixty-four births. During the same month of the previous year there were only forty. At Ponce, during the month of May, 1899, there were eighty-nine births. During the same month of the previous year there were fifty-two.

OTITIS OF THE EXANTHEMATA FROM THE STANDPOINT OF THE PEDIATRICIAN AND GENERAL PRACTITIONER.[1]

BY J. HENRY FRUITNIGHT, M.D.,
OF NEW YORK.

IN my experience, covering a quarter of a century and embracing nearly 5000 cases of the exanthemata, especially scarlet fever and measles, I have met with otitis media as the most frequent of the various complications which may occur during the course of these diseases. Of these patients, fully one-third were victims to a greater or less degree of this particular complication, and of these twenty-eight were bilateral. These cases naturally varied in type of severity both as individuals and as exponents of different epidemics. Nor was the frequency of the occurrence of the complicating otitis in a direct ratio to the severity of the general constitutional symptoms of the infection as, *a priori*, one might be led to expect. For often have I encountered this complication in cases of comparatively mild infection, and conversely, those exhibiting symptoms of a graver form very frequently escaped without this or any otner complication developing. In those highly malignant cases which run their course and terminate fatally in a period of from of eight to twenty-four hours, I have never seen this complication because the patient succumbed before a sufficient length of time had elapsed to permit its development. In general terms it may be affirmed that complicating otitis is very apt to be developed in those cases which have much irritation, congestion, or inflammation of the faucial mucous membrane, the anatomical relations primarily favoring this, and the activity of the specific infection promoting the development of this complication, and if adenoids or large tonsils be present this liability to the development of otitis is accentuated.

If these cases of otitis media complicating the exanthemata were always treated by the attending physician from the very onset of symptoms a great many of the patients could be cured with less suffering and with less chance of the occurrence of possible defective hearing or even total deafness. Too often when the patient complains of pain in the ear does the physician ignore the significance of this symptom, and later when the ear symptoms have become urgent it is recognized that valuable time has been lost in not having treated the complication when first the little patient began to complain, for I have often cut short an attack or at least mitigated its severity and preserved the patient's hearing by at once treating this complication at its very commencement. With me it is routine practice in every case of the eruptive fevers to watch the ears of the patients, knowing as I do how frequently otitis occurs as a complication and what deplorable results to the auditory apparatus may follow the affection. Those cases which are left untreated or which are perfunctorily treated will very often invite involvement of the mastoid process. In my hands this has never occurred, for my cases were always treated as soon as the first symptom appeared, thus cutting short the progress of the inflammatory process. If the attack be treated immediately upon its appearance I have not found it necessary to call in the aid of an otologist. Some cases which I did not see from the very beginning of the attack of the exanthem did require later the services of the aural specialist. I can recall one case in particular in which operation was performed by Dr. Herman Knapp, who went down through the mastoid process to the brain itself and removed an exudate from the outer surfaces of the lateral cerebral sinus. The child, marvelous to say, did not die. This child had developed a particularly severe otitis media during an attack of measles, resulting in this extensive caries of the mastoid process. She was not under my care during her attack of measles. It is but proper to say that this child showed lively traces of a tuberculous taint, and Dr. Knapp expressed the opinion that the mastoid disease was tuberculous in character.

And this suggests another point, for I observed that those children who were the subjects of a constitutional taint, as tuberculous, rachitic, syphilitic, and what would in former days have been designated scrofulous or strumous, were very prone to the development of this complicating otitis. I have already written *in extenso* concerning the treatment of complicating otitis media in the *Transactions of the American Pediatric Society* for 1889, and in an article read before the Northwestern Medical and Surgical Society of this city, and published in the MEDICAL NEWS, Vol. 69, 1896, so I shall not enter into its details. There are, however, a few points in the treatment on which I shall touch.

First, it is extremely important that scrupulous attention be given to the active treatment of the nose and throat in these cases, for thereby an attack of otitis is very often prevented. In regard to the question of paracentesis tympani I do not think that it is *always* necessary to incise the drum membrane. If, however, on inspection we can satisfy ourselves that the tympanum is projecting and is highly congested, and the patient is frantic with pain, then the membrane should be incised to relieve the engorged blood-vessels. These cases, however, are not so very common. When it has been necessary to do this I have made the incision myself.

[1] Read before the Section on Pediatrics of the New York Academy of Medicine, May 11, 1899.

Those cases which are slow to suppurate are in my experience the ones requiring this procedure. It has been seldom necessary in my experience to incise the drum membrane in suppurative cases, for many of such cases would perforate without warning. If the attendant does not have sufficient confidence in his ability to inspect the aural canal with the head mirror and hesitates to incise the membrane, then he should in the interest of the patient and for his own protection seek the advice and skill of the ear specialist.

The effort, however, should always be made to abort the attack and to hinder suppuration and perforation, because when the complication shall have gone to this extent the time needed to cure it will have been much augmented and the difficulties involved in its cure will have been increased many fold. As already intimated, those patients who are subjects of a constitutional taint, and in whom the otitis has been left untreated and allowed to go on to perforation, are very apt not to get well, but become chronic cases and lose their audition. For the accompanying otorrhea I have latterly followed the following plan of treatment: First, five drops of peroxid of hydrogen are instilled in the ear; after a few minutes this is flushed out with lukewarm water until the water returns clear, free from all turbidity; the canal is then carefully dried out with pledgets of absorbent cotton. Then three drops of an alcoholic solution of boric acid is put in the ear and allowed to remain there. The strength of this solution is from five to ten grains to the ounce of alcohol. In most cases this treatment has been successful in checking the purulent or seropurulent discharges, though I caution the nurse that the treatment must not be discontinued so long as there is a vestige of the discharge.

CLINICAL MEMORANDUM.

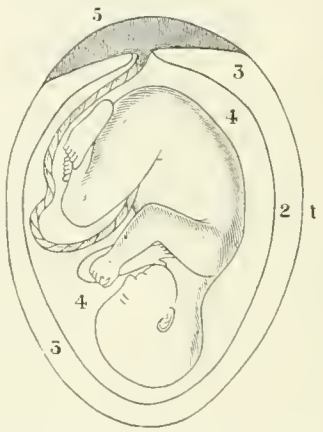
PERMANENT SEPARATION OF THE AMNION AND CHORION IN THE MATURE AFTERBIRTH, FORMING DOUBLE FETAL SACS.

By J. B. NICHOLS, M.D.,
of Washington, D.C.

In the early period of pregnancy the amnion and chorion are separate membranes and inclose separate (concentric) cavities, the amnionic and chorionic. Later, about the third month, the amnion becomes closely applied to the chorion, and the two membranes grow together, obliterating the chorionic space. It rarely happens that the primitive separation of the amnion and chorion persists throughout pregnancy, so that the fetus is enveloped in two separate sacs, the amnion internally and the chorion (united to the decidua) externally.

In April, 1899, I obtained for microscopical purposes, through the kindness of Dr. W. G. Suter, a human placenta with membranes and cord. The afterbirth was fully matured, and from a normal labor at full term; unfortunately further details of the maternal history could not, when later sought for, be ascertained. On examination this afterbirth was found to exhibit the abnormality of having the amnion entirely separate from the chorion, so that the fetus was surrounded by two separate sacs. The outer sac corresponded to the ordinary fetal membranes, proceeding from the margin of the placenta about the fetus; microscopical examination showed this to consist of the chorion and decidua vera, the amnion, which is ordinarily attached to the inner surface of the chorion, being missing. The inner sac was, as shown

Fig. 1.



Afterbirth with double sac. 1. Outer sac—chorion and decidua 2. Inner sac—amnion. 3. Chorionic cavity. 4. Amniotic cavity. 5. Placenta.

by the microscope, the amnion; it was given off from the placenta immediately around the insertion of the umbilical cord, and was thence reflected over the cord and fetus. A broad interval intervened between the amnion and chorion, and the surface of the placenta was not covered by amnion. The condition is exhibited diagrammatically in the accompanying sketch.

In such cases of double fetal sacs two separate discharges of the waters may occur, giving rise to a form of hydrorrhea gravidarum, or what was formerly known as "false waters."

The condition under consideration is a rare anomaly of the afterbirth, and one that is not specifically mentioned in standard works on obstetrics. I have found seven other cases of this abnormality on record, as follows:

Jörg, J. C. G. Schriften zur Beförderung der Kenntniss des menschlichen Weibes, 1812, part i, page 279.

Logan, C. A. *Leavenworth Medical Herald*, December, 1868, page 296. (two cases).

Chesney, J. P. *Leavenworth Medical Herald*, January, 1869, page 346.

Gilbert. *Detroit Lancet*, November, 1879, page 204.

Wood, Thomas. *Transactions of the Edinburgh Obstetrical Society*, Vol. XIII., page 126.

Bowen, W. Sinclair. *Transactions of the Washington Obstetrical and Gynecological Society*, Vol. IV., page 47. Dr. Bowen's specimen is in the Army Medical Museum.

MEDICAL PROGRESS.

Metastatic Pyemia from Trivial Causes.—Under the above caption, MCGREGOR-ROBERTSON and MCKENDRICK (*Practitioner*, May, 1899) give the most interesting details of a case of pyemia, which in two weeks brought about the death of an unusually vigorous man of sixty years of age. The only cause which could be ascertained for the entrance of the germs was a boil, which had arisen on the back of his neck a month previously, and which had entirely healed. Two or three smaller boils in the vicinity of the primary one were still active, but they were so insignificant that they were not considered etiologically, and the correct diagnosis was not made until the eighth day of the disease, when an abscess appeared in the right forearm. Two days afterward abscesses developed in the left wrist and right shoulder, and a pelvic abscess which gave no symptoms during life, was found *post-mortem*. In the beginning of the attack the fever was slight, the tongue was coated, and there was a very slight heart murmur. The suspicion of enteric fever was aroused. On the third day there was retention of urine, easily relieved by a silver catheter, and pelvic and abdominal examination showed no possible cause for the retention, other than a slight tenderness over the kidneys. The amount of urine was from that time on small, and the sediment contained some casts, so that nephritis was also considered. The low fever continued, and the heart's action became quicker, feebler, and more irregular, and when the abscess appeared in the arm, the diagnosis of malignant endocarditis was made. Multiple minute abscesses were found at autopsy in the lungs, liver, kidneys, and prostate gland. There was a moderate degree of old inflammation in the cardiac valves, but none of recent date. Medical literature contains the records of a number of cases similar to this one in which fatal pyemia followed an apparently trivial infection. The source of infection in such cases has often been in a felon, but in the large majority the pyemia has resulted from infection about the mouth or in the tonsillar region. An initial rigor, which in the case of the writers' was only a chilly sensation, is an almost invariable first symptom of the pyemia.

Removal of a Bougie from the Male Bladder.—GOLDBERG (*Centralbl. f. die Krank. der Harn. und Sexual-Org.*, April 22, 1899) divided a tight stricture with a Maisonneuve instrument. When he withdrew it, he found that the filiform bougie, which had acted as a guide, had remained in the bladder. The bladder was irrigated with mild antiseptic solutions for six days, a soft catheter being left in the urethra for two days. On the sixth day he saw the bougie through the cystoscope, lying across the urethral orifice. A small lithrotrite was passed and closed upon the bougie, which was readily extracted. Irrigations were kept up for a considerable time while the urethra was gradually dilated. There were no bad after effects.

Poisoning from Chloroform Decomposed by an Open Flame.—WINSLOW (*Boston Med. and Surg. Jour.*, May 11, 1899) assisted at an obstetrical operation in a room 12x 12 x 8.5 feet, in which there were three lighted gas-jets. Chloroform was used, but the fumes of the chlorin soon became so dense that the operation would have been abandoned had not all the windows been opened and ether substituted for the chloroform. Neither the physicians nor the patient suffered any permanent ill effects from breathing the gas, but the case ought to serve as a warning to others who administer chloroform in the presence of a lighted lamp or gas-jet, without providing for the escape of the poisonous vapors which are caused by the decomposition of the chloroform. The danger may be avoided by selecting a large, well-ventilated room, and by keeping the chloroform well below the light, using an inhaler such as Clover's, Junker's or Snow's, which prevents the escape of chloroform into the room. The most peculiar thing about this case was the fact that no one of the physicians present at the operation nor several others to whom they spoke about it, divined the origin of the irrespirable vapors, and ether was substituted for chloroform simply on the grounds that it was safer to use, as the operation would last longer than had been anticipated.

A Physician's View of the Indications for Operation in Cholelithiasis.—NAUNYN (*Centralbl f. Chir.*, April 22, 1899) affirms that cholelithiasis as seen in private practice is not so grave a condition as hospital practice leads one to think. He asserts that a favorable issue results in the large majority of cases without surgical interference. Certainly stones as large as a cherry can pass the common duct, and in many cases a fistula forms between the common duct and the duodenum, and then still larger stones may pass. Indications for operation are given as follows:

1. It is not justifiable to advocate operation in every case as soon as a diagnosis of cholelithiasis has been established, for operative interference does not guarantee a permanent cure, since stones may be left behind, or others form.

2. Cases of acute cholecystitis with a greatly distended gall-bladder, as well as chronic cases of hydrops of the gall-bladder should be submitted to operation.

3. In cases of chronic recurrent cholelithiasis, and

4. In cases of obstructive jaundice operation should not be resorted to until a thorough Carlsbad treatment has failed.

Gastrocolic Symphysis.—BOUVERET (*Rev. de Med.*, April, 1899) describes under the name of gastrocolic symphysis, the drawing together of the stomach and transverse colon, which often follows chronic peritonitis either of a general character, or when localized in the region above the umbilicus. Extreme cases in which the stomach and colon are glued together throughout the whole length of the former are rare. In the ordinary cases, the attachment is not so close but may still give rise to a set of symptoms sufficiently definite to warrant

their grouping under a single name. Bouveret saw eight cases, in all of which the exciting cause was either cancer or ulcer of the stomach, and in all of which the adhesions were situated at the pylorus and extended to a greater or less distance along the greater curvature. The symptoms of pyloric stenosis were aggravated by the attachment of this part of the stomach to the liver, pancreas, or gall-bladder, while if the adhesions had caused the immobilization of a part of the stomach they set up the most intense pains. Adhesion to the liver was especially common when the trouble was due to a simple ulcer. There are two complications of this affection which can terminate life, a gastrocolic fistula and occlusion of the intestine. From a comparison of histories of sixty-two cases of fistula the following symptoms were noted: Fecal vomiting, the passage of undigested food (lientery) similarity of the vomited matter and the stools, profuse diarrhea, thirst, rapid emaciation, a fecal odor to the breath and to eructations, the sudden cessation of vomiting which has existed for a long time, or the sudden disappearance of a tumor which had existed for a long time, and the vomiting of injections. To these signs may be added the evidence offered by the inflation of the colon with air, through the rectum, and the results of the chemical examination of the stools. These signs do not all have an equal value. However, if the fistula is large enough to permit the free passage of fluids, the diagnosis will usually not be hard to make during life. Stenosis of the intestine may be produced by a band, by circular constriction, and by abnormal fixation, three factors which will be likely to be combined in various ways. The symptoms are those of obstruction elsewhere in the large intestine. Occlusion is usually incomplete for a long time, and the death is therefore a lingering one. In some patients it is possible to make out that the increased peristalsis due to the obstruction has already begun in the cecum and ascending colon but has not yet extended to the small intestine. This partial peristalsis of the large intestine has a great value in diagnosis. It is well known in connection with pyloric obstruction, the stomach alone being involved in the increased movements; but increased peristalsis of the small intestine has also been observed, though it is certainly rare. General peristalsis is the fourth variety of peristalsis and is of less value in diagnosis than the partial ones.

In operating upon a patient with gastrocolic symphysis a median incision above the umbilicus is to be preferred.

THERAPEUTIC NOTES.

Use of Salt Solution in Eclampsia.—ALLEN (*Amer. Jour. of Obstet.*, May, 1899), having treated a number of eclamptic patients without the use of saline infusion and also a number by this method, says that it is impossible to realize its great advantages unless one has watched its results. He advocates for *pre-eclamptic* treatment, thorough purgation, and warm baths twice a day, a milk and water diet, and sedatives. If the symptoms do not improve, interference with pregnancy is justifiable. In cases seen after convulsions have begun, his *eclamptic* treatment is to give morphin at once, and inject into the bowel 1 dram of bromid and 40 grains of chloral, to anesthetize the patient, using as little chloroform as possible, and to empty the uterus, by forceps or version, to allow the patient to bleed from the uterus for a time and if not enough blood is lost in this way to open a vein. As soon as possible after delivery he introduces 700 c.c. salt solution under each mamma and if necessary he repeats the injections daily for several days. The only drug that seems efficient to move the sluggish bowels in this disease is croton oil in large doses. Two drops may be given in 2 drams of olive oil, the latter preventing the severe irritation which croton oil sometimes causes. As soon as the patient rouses sufficiently she is given dram doses of Epsom salts every hour, or an enema. Wet and dry cups may be applied over the kidneys, or a half ounce infusion of digitalis given every four hours. The diet is exclusively milk. A hot air bath or a wet pack is useful in stimulating the skin. During convalescence a tonic is needed.

An Internal Plate for Ununited Bones.—POTARCA (*La Presse Med.*, April 19, 1899) cuts down upon an ununited fractured bone, squares the two ends, and holds them in a correct position, closely approximated, by a thin metal plate which is screwed fast to each fractured end, just as one might mend a broken cane. The after treatment is very simple. Held together so accurately, the bones quickly unite, and when union is sufficiently solid, the plate is exposed by a new operation, the screws taken out, the plate removed and the new wound allowed to heal. There are no complications to be feared, if the plates are capable of being sterilized, and are made of some metal which will not decompose or form poisonous salts in the fluids of the human body. Nickel, almost pure, answers these requirements better than silver, platinum, aluminum, or copper. This method of treatment is also recommended in recent fractures in which reduction cannot be obtained or cannot be maintained. Thanks to the X-ray, the relations of the ends of the bone can be determined with exactness, and an immediate operation be performed if it is found to be desirable.

The Thyroid Gland in Infectious Diseases.—ROGER and GARNIER (*La Presse Med.*, April 19, 1899) examined the thyroid glands of thirty-three patients who died from infectious diseases—scarlet fever, measles, diphtheria, smallpox, typhoid fever, cerebrospinal meningitis, and septic peritonitis. It was not always possible to say how much of the alteration in any given case was due to the primary disease, and how much to the fatal complications. In general, however, there was congestion and hypertrophy of the thyroid, with an increased and altered secretion, and in the only smallpox case examined, and in one of the diphtheria cases, there were foci of parenchymatous hemorrhage. Most of the changes were of such a character that, had the patient lived, they could easily have been recovered from; but other lesions suggested a permanent derangement of the gland though just how the system could be affected thereby is impossible to state with our present knowledge of the pathology of the thyroid.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

YELLOW FEVER; ITS DIAGNOSIS AND QUARANTINE REGULATIONS.

OUR relations with Cuba and the West Indies generally have become so intimate that every one has been looking forward with no little dread to the increased possibilities of yellow fever being imported into the States during the present summer. The recent outbreak of the disease in the garrisons at Santiago and Cienfuegos, although limited in extent and rapidly brought under control, adds to the apprehension.

Dr. Lainé's article, which we publish this week, while giving the important practical points for the speedy recognition of yellow fever makes it clear that even, in experienced hands, the unfailing detection of the disease at its inception is a very knotty problem and one that cannot be solved with the ready facility that popular tradition usually assumes.

The points given by Dr. Lainé cannot fail to be of the greatest service, however, and the very fact that those who are most familiar with the disease deprecate the idea that any assured means of early diagnosis of yellow fever exists, in the absence of an epidemic, will make medical men when suspicious cases come under their care all the more careful of making definite declarations until assurance beyond doubt or cavil is at hand. It is probable that owing to increase of commercial relations between the West-Indian islands and the mainland a certain number of actual cases of yellow fever may be imported and that a number of insolation and choleraic cases that develop shortly after landing will be open to the serious suspicion that they are yellow fever. Under either of these circumstances it is important that diagnosis should be carefully considered and be absolutely assured before made public. The public health and the commercial interests of the country are dependent on it.

It is unfortunate that we have not a uniform system of quarantine. Quarantine regulations at present are dependent on State governments and differences are very notable. So long as the responsibility for the public health of the country is thus divided among many, loopholes for the entrance of epidemic disease are liable to be left unprotected, and the lack of a National Bureau of Health will be more and more felt in the immediate future. The Marine Hospital Service is doing all that can be expected of it, with its inadequate means and unsatisfactory authority. It is certain that the work accomplished by it even under these trying conditions is making clearer the advisability of committing the care of public health to a central bureau.

The State government of Georgia has recently turned over to the United States Marine Hospital Service its quarantine at Savannah. The effective work done by this department in the Southern States at times of yellow-fever invasion during the past few years, certainly justifies this action and stamps it as a step in the right direction. It is to be hoped that other State governments will see their way to a movement in the same direction. Under present conditions and without the National Bureau of Health that we should have, this voluntary appeal to the Marine Hospital Service seems the action most suited to secure easily and promptly the uniformity of quarantine regulations.

INIZATION OF THE SPINAL CORD.

now nearly sixty years since the introduc-
the habitual employment of narcosis during

operations by means of ether or chloroform. In view of the many inconveniences and dangers attendant on anesthesia produced in this way it is surprising that, save for minor alterations, the methods in use to-day are practically those of Long, Simpson, and their contemporaries. The only real advances have been the facilitation of the first stage of etherization by the primary induction of laughing-gas narcosis, the combination of oxygen with the anesthetic, and improvement in the form of inhalers. Experience has shown that the various mixtures of ether and chloroform with the higher members of the petroleum group offers few advantages and real dangers, so that the ideal method of causing insensibility during major operations has not yet been attained.

A step in advance seems to have been made, however, by Bier of Kiel who, in the *Deutsche Zeitschr. fur Chirurgie* for April, relates his experience with an entirely new application of a local anesthetic to produce general anesthesia. By the bold expedient of throwing small quantities of very dilute cocain solution (0.005–0.01 gm. of cocain) directly into the spinal canal he attacks the nerve-roots and ganglia themselves as well as the non-medullated nerve-trunks before their emergence from the spinal column and produces satisfactory anesthesia of the whole body beneath the nipple line. Insensibility is complete seven or eight minutes after the injection, which is done after the manner of Quincke's lumbar puncture, made painless by a preliminary Schleich's infiltration, and continues for about three-quarters of an hour. Strange to say, heat and cold perception and also the touch and pressure senses are preserved, but all impressions of pain are entirely obliterated. Because of this, and inasmuch as it seems incredible that the entire thickness of the large nerve trunks should be permeable by the solution in so short a time, the inference is drawn that the pain-conducting fibers are placed at the periphery of the nerve-bundle.

Bier performed in this way such severe operations as osteoplastic resection of the ischium, knee-and [illegible] ankle-joints, necrotomy of the tibia, resection [illegible] femur, etc., to the perfect satisfaction of the p[illegible]ptic [illegible]tes. By experiment on himself and a colleague [illegible] proved that the anesthesia was absolute and [illegible] duction unaccompanied by unpleasant sensat[illegible]

Unfortunately for the vogue of the new method, however, the after effects are quite as undesirable and much more prolonged than those following chloroform or ether, and consist in dizziness, severe headache, nausea, and vomiting. As these symptoms do not put in an appearance till a number of hours after the operation it is assumed that they are due merely to the disturbance of the cerebrospinal system and not to any direct toxic effect of the drug, and it seems probable that modification of the solution employed may eliminate these difficulties.

While in its present form suitable only for individual cases where the use of the usual anesthetics is inadmissable, the idea is a very promising one and opens up a most suggestive field for investigation.

ECHOES AND NEWS.

Another Honor for Dr. Jacobi.—The Society of Obstetrics, Gynecology, and Pediatrics of Paris, at its session, June 2d, elected Dr. Abram Jacobi to foreign membership.

Oysters and Typhoid Fever.—The report of the Health Officer for Brighton, England, states that "in 41.8 per cent. of the cases of typhoid fever occurring in Brighton during 1898, there is a high degree of probability that sewage-contaminated shell-fish were the cause of the attack." This percentage is higher than in previous years.

Dr. Cleaveland Free.—The case against Dr. Trumbull W. Cleaveland, who was charged with having caused the death of the child Irene Carhart, by improper prescribing, was dismissed on June 23d, the defense having put none of its witnesses or experts upon the stand.

Cerebrospinal Meningitis in the United States. — At Shreveport, La., two deaths from this disease occurred during the week ending June 10th, making a total of twenty-nine deaths from this cause since January 1, 1899. In the District of Columbia five deaths were reported during the week ending June 20th. At Philadelphia for the week ending June 17th, four cases and three deaths were reported.

A Yellow-Fever Cure?—After independent experiments extending over a period of two years, Dr. Alvah H. Doty, Health Officer of the Port of New York, has produced a serum corresponding to that of Professor Sanarelli which he considers both prophylactic and curative in yellow fever. While using this serum it would be just as well not to neglect principles of sanitation such as General Wood has found an almost perfect safeguard against the disease in Santiago.

Germany's Object-Lesson in Vaccination —Germany, with a population in 1871 of 40,000,000, lost during that year 143,000 lives from smallpox. In 1874 the German Government enacted a law making vaccination obligatory during the first year of life, and revaccination obligatory

at the tenth year. The result was that the mortality from smallpox diminished rapidly, until now its victims number only 116 a year, and these cases are confined almost exclusively to the frontier towns.

Contagious Diseases in New York City.—The Board of Health makes the following report for the week ending June 24, 1899: Measles, 330 cases and 12 deaths; diphtheria, 198 cases and 30 deaths; laryngeal diphtheria (croup), 7 cases and 3 deaths; scarlet fever, 130 cases and 14 deaths; smallpox, 2 cases and 2 deaths; chicken-pox, 21 cases and 0 deaths; tuberculosis, 165 cases and 145 deaths; typhoid fever, 16 cases and 5 deaths; cerebro-spinal meningitis, 0 new cases and 7 deaths.

The "Index Medicus."—The widespread regret felt because of the possible abandonment of the *Index Medicus* has been partially dispelled by the prospect of the work being assumed by the American Medical Association. The resolution introduced at the recent meeting at Columbus that the Association take upon itself the editing and publishing of the *Index Medicus* has been referred to the trustees, who have taken it under serious consideration. As far as the benefit to the medical profession of America, or even to the world, is concerned, the Association by undertaking this work would accomplish far more than by devoting its efforts and finances to the proposed erection of elaborate and expensive buildings.

The "Philadelphia Medical Journal" and the American Medical Association.—Our Philadelphia contemporary takes a most hopeful view of the future prospects of the Association. It says: "It is character rather than numbers that inspires us with hopefulness Even in such a matter as personal ethics and dignity there was at Columbus a most noteworthy absence of what has previously been an altogether too conspicuous presence of the guzzlers and 'all-nighters.' There were even strange stories of '*Nothing stronger than lemonade, please, this year.*" and the banquets, even that of the so-called American Medical Editors, were free from stories in which the delight in witless filth has often been an astonishing element of attractiveness. There is plainly to be an end of the 'dry-smoker' and the roysterer."

Convention of Homeopathic Physicians.—The fifty-fifth annual session of the American Institute of Homeopathy opened in Atlantic City, New Jersey, on June 20th. There were over 1400 Hahnemannians in attendance. A report was adopted recommending that interference of opticians with the medical profession be deprecated. The following resolution was offered by General M. O. Terry of Utica, N. Y., ex-Surgeon-General of the National Guard of New York: "*Resolved*, That in the opinion of this association, the oldest National medical organization in the United States, the condition of the country and its standing among the progressive nations of the world demand for its medical department a position in the Cabinet equal in all respects to the other departments of the Government."

Criminal Attempt to Avoid Service in the German Army.—The wealthy young men of Germany present a striking contrast to the same class in our own country. It is reported from Cologne that a number of prominent physicians and wealthy young men who have succeeded in being exempted from military service, unlawfully, are involved in a criminal case which is assuming alarming proportions. There are now seventy-two defendants. The trick in most instances was to render the men called for physical examination temporarily unfit by administering strong doses of heart depressants sufficient to produce fluttering of the heart and other alarming symptoms. The Emperor has ordered a thorough investigation, without regard to whom it may hit. Several of the accused men are sons of rich Cologne bankers.

Unselfish Devotion to Medical Duty.—The English medical journals commented recently in glowing terms on a very striking example of unselfish devotion to duty on the part of an English medical man. Dr. R. J. Burns of Sunderland was summoned to attend a man who had swallowed some phosphorus paste in beer. He came provided with a stomach-pump but the instrument unfortunately was out of order. The doctor passed the stomach-tube and proceeded to empty the man's stomach by suction on the tube. His patient recovered only temporarily though so faithfully were the doctor's efforts that he himself has since been prostrated with some symptoms of phosphorus poisoning, partly from the effect of the fumes developed during the operation, and partly from actual absorption of the phosphorus through his oral mucous membrane. He has, however, now entirely recovered.

American Troops in the Tropics.—Major George G. Gross, U. S. A., in a paper read at the recent meeting of the American Medical Association said: "In the selection and care of troops for the West Indies none but entirely sound men should be sent to these islands. No recruit under twenty-one years should be sent, and it would be better to make the minimum age twenty-two years. There should be no 'toughening' the troops on Florida sand-banks or by forced marches under a Virginia or Georgian sun. The transport service must be improved. At once, reaching the tropics, the men must be housed. The rations should be modified. Still further changes are needed in the uniform. Something lighter than the khake uniform for wear on marches and in the hottest weather. While it is true that the history of the Caucasian race in the West Indies is not encouraging, yet these islands produced a Hamilton and a Josephine. Bad laws and bad social conditions, rather than the climate, have probably defeated the ends of Nature."

The William F. Jenks Memorial Prize.—The fifth triennial prize of $500, under the deed of trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on "The Various Manifestations of Lithemia in Infancy and Childhood, with the Etiology and Treatment." The prize is open for competition to the whole world, but the essay must be the production of a single person. The essay, which must be written in the English language, or if in a foreign language, accompanied by an English translation, must be sent to the Col-

lege of Physicians of Philadalphia, Pennsylvania, before January 1, 1901, addressed to Richard C. Norris, M.D., Chairman of the William F. Jenks Prize Committee. Each essay must be typewritten, distinguished by a motto, and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay. The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year. The committee reserves the right not to make an award if no essay submitted is considered worthy of the prize.

Aseptic Duelling.—The newspapers announced recently that the well-known French author, Catulle Mendes, had been wounded in a duel, the grounds for which had been the fact that he held the contradictory proposition to his opponent in the very important historical question, Was Shakspeare's Hamlet fat? Some of the details of the duel are of considerable interest to medical men. For instance, whenever the sword of either one of the duellists touched the ground the duel was instantly interrupted until the blades had been thoroughly sterilized by being passed through the flame of an alcohol lamp. What was especially feared and the reason for these minute precautions was contamination with tetanus bacilli. Not long ago a French surgeon issued a book giving the indespensable regulations for the proper conduct of a surgeon when summoned to a duel, which included the most rigidly surgical sterilization of the duelling swords, and their careful preservation in a state of the most absolute asepsis until the moment they were handed to the combatants, special care being prescribed that no hands came in contact with the blades before they were put to use. The interruption in order to resterilize whenever possible contamination is suspected is the very latest wrinkle and all up to date. Specialists in duelling surgery will, it is hoped, take note of this latest humanitarian addition to the surgical technic of the duel.

The State Board of Charities and the Society for the Prevention of Cruelty to Children.—Justice Barrett of the Appellate Division of the Supreme Court handed down a unanimous opinion on Friday, June 23d, declaring that this Society is a charitable or eleemosynary institution, and as such subject to the powers of visitation and inspection of the State Board of Charities. The very fact that such societies are clothed with peculiar and even extraordinary powers instead of indicating that the Legislature or the people meant to withdraw these societies from the supervisory powers of the State Board of Charities seems rather to suggest a conclusive reason why they should be supervised, and indeed quite as vigilantly as institutions possessing less power for good or evil. Mr. De Lancey Nicoll, counsel for the Society, says that the present decision will not be accepted as final, but that the matter will be taken to the Court of Appeals. The investigation into the affairs of the Society which is being conducted before Albert Stickney brings out clearly that the police department and the district-attorney's office consider the Society to be not only useful to them but needful. At least one judge and one police magistrate declared that the Society's records were practically indispensable when the question of the disposal of children came up before them. All of them were asked if they thought that a city department could accomplish as well the work now done by the Society, and replied in the negative. Certain recent newspaper allegations as to the shirking of taxes by the Society were shown on direct evidence to be practically without foundation.

Obituary.—Dr. Thomas Osmond Summers, late surgeon-major in charge of the fever hospital at Santiago, and a noted yellow-fever expert, committed suicide by shooting himself through the head at St. Louis, June 19th. Despondency caused by the fancied lack of appreciation of his services by the Government during the Spanish War is supposed to have been the cause. Dr. Summers was Professor of Anatomy in the St. Louis College of Physicians and Surgeons, and was the author of several standard medical works. He gained an enviable reputation in his successful management of the yellow-fever epidemic at Memphis in 1878. The agony of mind that Dr. Summers evidently suffered previous to committing the fatal act was shown by a most touching farewell letter to his wife, and his farewell to earthly existence is forcibly and poetically expressed in the following lines, which were found after his death:

PERDITI VITUM—VALE MUNDUM.

Good-night, Old World—Good-by to all your joys,
Your sorrows, pleasures, passions, pomps, and noise.
I leave you for the eternal silence of stars;
The deepness of unbounded space where bars
No longer hold the soul in durance vile.
Where naught can wound and nothing can defile;
Where the pure spirit shall despise the things
The sense on earth hath loved.
On wings bathed in the ether of eternity,
How sweet to feel from every passion free—
And yet it is an awful leap to take.
Into the great unknown perchance to wake
To greater woes, indeed, than those we have
And hoped to bury in the silent grave.
But still the greater majority is there.
Why then should we turn pale with fear?
Or tremble when the hour supreme has come,
As soon or late it must?—Man's final home—
The grave—at least gives rest from troubles here,
And we may hope for sweet oblivion there.
Then, Charon, come, I signal thee to-night,
Come—row me o'er the Styx, I've lost life's fight.
OSMOND.

Another Miracle by the Osteopath!—That the age of miracles or fairy tales has not yet passed away is shown by the following, which was telegraphed a few days since from New York to a Western newspaper, and duly appeared in its columns: One of the most unusual operations yet recorded in surgery was performed recently on a young woman in this city, by which was effected the cure of a case of appendicitis. No knife was used, no medicine, no poultices, no ice-packs—none of the usual methods of physicians to treat this most serious of ailments. So simple was the method employed that only eight minutes elapsed from the time the physician reached the patient until he had completed his work, and, as he believes, successfully. The young woman is twenty years old, and belongs to an excellent family in Harlem. The doctor who performed the operation thus explains

the treatment: "The method of treatment is the one used by all osteopathists and has been in use by them for some time." To demonstrate, the doctor placed the thumb of the reporter's left hand flatly in the palm of his right hand. Then he slapped the palm of the hand smartly against the broad of the thumb. "The hand represents the psoas muscle," he said, "and the thumb the appendix. We produce a spasmodic contraction of the psoas magnus, like the slapping of the palm of the hand against the thumb. This forces the foreign substance from the appendix, and relief follows immediately. Just back of the appendix is the largest muscle in the human body, known as the psoas magnus. It is attached to the femur or big bone of the leg, and is the muscle by which one can revolve the leg as a pivot at the heel. It is this muscle which is made to do the trick of emptying the appendix. Using the fingers of one hand to hold the walls of the abdomen in place and to prevent a rupture of the delicate internal structures, with the other hand a spasmodic contraction of the psoas magnus is brought about, which snaps it against the appendix and is said to force out of that organ whatever of foreign substances it may contain." Angels and ministers of grace defend us in this the dawn of the Twentieth Century!

Dispensary and Hospital Abuse.—The agitation upon the subject of the abuse of dispensary and hospital charities, which has been created by the medical profession and vigorously maintained during the past few years, shows evidence of bearing fruit. The Dispensary Law, passed by the New York Legislature last winter, has placed in the hands of the State Board of Charities the power to correct abuses. This board, together with the New York City comptroller, is now taking active steps looking to immediate reformation of the present wasteful methods. Mr. Coler, the city comptroller, arraigns the present system of distributing charitable funds as follows: More money is contributed for charity than can be expended properly for charitable purposes and the result is the creation of a class of artificial dependents. (2) Enormous sums intended for the relief of the poor are wasted in costly buildings and large salaries. (3) Private charities, partially supported by the city, draw from the institutions wholly under city control to such an extent as to impair the latter's usefulness. (4) No adequate account is made of money received and expended. (5) Certain charities are run for the principal object of drawing money from the city and spending it. In support of the first count in his indictment the comptroller points out that while the pauper population of the city amounts to only one per cent. of the total, no less than seventy per cent. are receiving medical treatment free of charge through charitable institutions. Public and private charity expends annually, in New York State, more than $20,000,000, in the support of unfortunates who are not criminals. More than one-fifth of this great sum goes for salaries alone. Speaking generally it costs, under the present method, $25 to distribute $75 in charitable work. Many of the charitable institutions of New York City make a practice of paying canvassers for contributions a percentage of all the money they bring in. The comptroller points out a striking instance of abuse in this connection. He is an honorary vice-president of the Moderation Society, the purpose of which is to supply ice-water in summer in order to prevent the use of intoxicants. The city appropriated for the use of this society, $250. A few days later Mr. Coler received a letter saying, that no doubt he would be glad to know that the man who brought the city's check to the society received $25, or ten per cent. of it, for his trouble.

CORRESPONDENCE.

THE AMERICAN MEDICAL STUDENT ABROAD.

MEDICAL WORK FOR WOMEN IN VIENNA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Practically, a woman's opportunities in Vienna for regular medical work are as great as those of a man, although a few professors still refuse to admit women to their lectures and operations. The university of Vienna, founded in 1365, conferred its first degree upon a woman—that of Doctor of Medicine—in 1897.

We made it a rule to ask permission of each professor, *docent*, or assistant, before entering his clinic or operating-room, and thus were always sure of a friendly reception. We have been told that failure to observe this rule sometimes resulted disastrously. Letters of introduction from eminent physicians may be of great value; letters from former students are generally disappointing, because, in the rapidly changing classes, names are likely to be forgotten. A fair knowledge of German is, of course, indispensable to one's best work. If necessary, it is an actual saving of time to devote oneself, at the outset, to serious study of the language.

The unlimited university course can be entered at any time by making application to the medical department of the university, but the courses most popular with foreign doctors are private and are difficult, sometimes impossible of access. Many of these courses are organized, and in a measure controlled, by English or American doctors, to whom application must be made. It is advisable to arrange some time in advance for a place in a popular course, as places have often been engaged months, even a year before they were to be used. By writing to the Anglo-American Vienna Medical Association, I Landesgericht-strasse 12, one can obtain the latest information. The regular university program and programs for vacation courses are useful in planning one's time.

The work in medical diagnosis is unequaled. It would be difficult to imagine a more thorough system of physical examination and instruction. One is filled with admiration for the skill of men who have for years enjoyed the advantages of a free use of unlimited material, with opportunity to test the diagnosis of every fatal case at the autopsy-table. The hospital wards are freely accessible to students, and one can spend hours daily in the study of cases with the most advanced aids to diagnosis at one's command. The clinical material both as to adults and children is enormous. There are fine advantages for studying infectious diseases, especially scarlet fever

and diphtheria. The post-mortem room is open to all students.

In the pathological and bacteriological laboratories there is a vast quantity of fresh material, with skilled direction in exhaustive macroscopical and microscopical study of pathological findings. Advanced students desiring to do research work are cordially welcomed, and assisted in making an *arbeit* worthy of the department.

Excellent diagnostic courses in surgery, with operative work on the cadaver, are obtainable. It is possible in a few clinics to get minor surgical work, and some who have been willing to serve a couple of years in a clinic have had the privilege of assisting the professor at major operations, and also of performing a certain number.

The courses in gynecology are very good and include examinations under ether, some small operations, and general treatment; larger operations are almost out of the question for doctors not regularly appointed as *operateurs*. The obstetrical advantages are confined to diagnostic work, with operative work on the *phantom* and cadaver. By special favor and large expenditure of time one may be allowed some deliveries, with a case or two of low forceps. The number of *operateurs* has been so much increased during the past ten years that there is nothing left for students. By securing permission to visit the three obstetrical clinics—total deliveries in a year, nine or ten thousand—one can, in a short time, watch a large number of cases and see considerable interesting operative work.

On special subjects there are numberless courses, some of which are exceptionally good: for instance, exceedingly valuable skin clinics, and embryological and anatomical courses on special organs finely illustrated. One great advantage of medical work in Vienna is its concentration, making it possible to take a variety of work without the loss of time entailed in constantly traversing a great city.

The criticism often justly passed on American students is that they spread their energies over too much ground, and by a multiplication of courses fail to get the best advantages and privileges from any.

Expenses naturally vary with a student's individual needs and tastes. The fee for each member of a course in obstetrics, gynecology, and operative work is 2½ guldens, or about $1 per lesson; for other work generally 1 gulden. The tickets for university courses cost only a nominal sum. German lessons range from 40 to 50 cents an hour, and sometimes it is possible to exchange English for German lessons. Room and board may be obtained for from $25 a month up, exclusive of various fees.

In conclusion let me say that we were strongly advised not to go to Vienna to study as the prejudice against women in medical work was said to be too strong to make such an attempt worth our while. On the contrary, we cannot speak too highly of the unfailing kindness and generous hospitality extended to us as colleagues during a two-years' stay.

ANGENETTE PARRY.

NEW YORK, June 19, 1899.

RELAPSING MEASLES.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I have noticed in recent issues of the MEDICAL NEWS your remarks anent relapses of measles, also Dr. Coleman's letter.

We have just had an epidemic of measles of an extremely severe type, and I have been much interested in two cases, a brother aged fourteen, and sister aged ten years, who are neighbors. Both of the children, so their mother assured me, had undoubtedly cases about nine years previously, and were the only two cases out of six that did relapse.

The boy was first attacked and had an extremely severe spell, with grave symptoms. He made a beautiful recovery, but about sixteen or seventeen days afterward had a mild attack, the fever lasting only a day or two, and the eruption disappearing in about forty-eight hours. The little sister had a very mild spell, fever three or four days, with an eruption thinly spread over entire body. She was soon up and at school again. About one week later she developed the initial symptoms, and had one of the severest attacks I ever witnessed. She is now up and about, but wears dark glasses to protect the eyes.

These two cases occurring under my eye offer this suggestion: Are not some people more liable, or rather more sensitive to infectious fevers? Is it not possible that relapsing measles occurs most frequently in those not rendered immune by a previous attack?

I offer this as an observation and trust others will be heard from on the subject. J. C. BALLARD, M.D.

NATCHEZ, MISS., June 20, 1899.

CONGENITAL ABSENCE OF UTERUS, OVARIES, AND THE CLITORIS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—We wish to report an unusual case of congenital absence of the organs of generation— uterus, ovaries, and also the clitoris. Jeanette T., aged twenty years, mulatto, well developed; came from a healthy family. The general figure is that of a slender boy—shoulders square, hips narrow, legs slightly bowed. Mammary glands well developed. External genitals appear natural. The parts are well covered with hair, with growth peculiar to females.

Digital examination revealed an apparent imperforate hymen, tough and fibrous, with slight elevation, or folding near the center. On chloroforming, and using Sims' speculum, the following conditions were seen: The vagina was only a shallow pocket, with the meatus opening very near the center of the canal. The lesser labia appeared normal. No clitoris could be seen or made out.

The bladder was emptied with a catheter, and using the instrument as a sound examination was made with a finger passed into the rectum. As high up as it was possible to reach neither uterus nor ovaries could be felt. Nothing intervened between the finger and sound save the perineal body low down, and above only the walls of the rectum, and the bladder. After close search in this way and bimanually none of these organs could be made

out. The pubic arch was an acute angle (exaggerated male), the anteroposterior diameter not more than 2½ inches.

This woman (?) has never menstruated. Has suffered with periodic headaches, and has had an occasional attack of drowsiness. She stated that she had never felt passion for man or woman.

J. A. JAMES, M.D.,
T. H. JAMES, M.D.

CHERAW, S. C., June 17, 1899.

PARTIAL CONSCIOUSNESS DURING ANESTHESIA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In the issue of your journal for May 20, 1899, appeared a communication from Dr. H. H. Stoner, in explanation of the possibility of retaining consciousness during anesthesia in so far, at least, as auditory impressions are concerned, that in spite of its "extremely fanciful hypothesis" has a great deal in its favor. It may be true, as you said in your editorial foot-note, that the neuron theory has never been extended to the psychic phenomena in print, but I must admit that I have personally held this opinion for some time.

We know that brain substance is composed of neurons and neuroglia or brain-cells and matrix, each brain-cell with its dendrites and its axis cylinder. The researches of Max Schultze have proven that the nerve fibrils composing the neuroglia or ground-substance of the brain are continued directly through the axis-cylinder of the cell, thus forming a direct means of communication between all active brain-cells having medullated axis-cylinders or neuraxons. Sir W. R. Gowers[1] has shown that there is every reason to believe that the individual brain-cells or neurons have no direct communication by means of their dendrites, but lie separately embedded in the matrix, each neuraxon in close proximity to a dendrite, both possessing an afferent and efferent molecular motion respectively. Now, if besides this afferent molecular motion each dendrite has an actual motion, capable of making contact with its nearest neuraxon—and there is no reason why this should not be, though it might be hard to prove—we could then understand the mechanism for the transmission of nerve impulses through the brain. If we look upon the brain as a vast battery composed of millions of cells, each cell (neuron) having a positive (neuraxon) and negative pole, the latter having several shunts (dendrites), lying close to but not touching the opposite pole of its nearest cell; if we assume some simple arrangement by which this positive pole becomes magnetic as soon as the cell is thrown into the circuit, thereby attracting the nearest negative shunt of some other cell and so throwing it into circuit, and so on from cell to cell, we have a simple explanation of impulse transmission in the brain, and this theory, whether right or wrong, must at least be considered plausible. Now, if this holds good for the sensory-motor part of the brain, there is no reason to doubt that it also holds good for the ideomotor part, the psychic centers in the cortex: for psychic, sensory, and motor phenomena are as interconvertible as the phenomena of electricity, light, and motion. As one writer has said: "We think as we feel, or think we feel; and feel as we think. If we feel a pain, we think we are ill; and if we think we are ill, we feel ill." If hypnotism has been of no other practical value, it at least has proven the correctness of the above statements, and all students of this psychic condition know how easy it is to change psychic, sensory, and motor phenomena one into the other.

By means of this neuron theory I have been enabled to explain to myself, at least to my own satisfaction, how Heidenhain's theory of cortical inhibition during hypnosis might be the correct explanation of these phenomena. I advance this not as an original idea, for in this age of omnivorous reading one hardly knows when one has an original idea, but as the outcome of reading and thinking. Those who have studied hypnotism not only from a practical but from a theoretical point of view, no doubt have come to the conclusion that hypnosis is a mental state similar to that of preoccupation and reverie, when that mental activity called "attention"—I say activity, because it is the result of will—is focussed on any one thought or line of thought and thereby frees the lower sensory-motor centers from the control of volition, enabling them to perform work automatically and without conscious knowledge. If the theory of dendrite make-and-break contact advanced above be true, it can easily be seen how in the ideomotor centers of the cortex this dendrite contact of the neurons could be brought about by the psychic activity of attention, and that when this activity is focussed, as in preoccupation or reverie, or paralyzed, as in hypnosis, the entire mass of psychical neurons would have to become isolated from the rest of the brain cells, and that there would have to result an absolute and utter inhibition of volition on the one hand and an equally absolute inability to consciously recognize sensory irritations, such as pain, on the other; such at least is the experience of all students of hypnotism, whether the theory advanced in explanation of it is true or not. Those who have studied the practical side of hypnotic phenomena know that chloroform is a great help in producing hypnosis where a simple focussing of the attention with proper suggestions has no effect, in fact the inhalation of a few drops of chloroform with the simple suggestion of "shut your eyes and go to sleep" repeated a few times, often has the effect of at once producing deep hypnosis with peripheral anesthesia. If the anesthetic is now withdrawn, the patient is in the hypnotic state, the muscles generally cataleptic, and under the control of the operator's voice; if the anesthetic is pushed beyond this, the catalepsy disappears and the muscles become flaccid with absolute anesthesia, so that there is not even a corneal reflex, but the patient is still in hypnosis, subject to the operator's control, remembering frequently everything that happened in this state on waking, and waking at once at the operator's command. If the chloroform is pushed beyond this stage, then results chloroform narcosis, and the subject is no longer under the operator's control.

Such is my experience with some six or seven cases,

[1] *Brit. Med. Journal*, November 6, 1897.

the first one happening some years ago, when I had a simple minor operation to perform and intended to use hypnosis for anesthesia, but could not get my patient under control, so decided to give chloroform. When fully anesthetized, as I thought, I handed the inhaler to an assistant and proceeded with the operation, amputation of a finger. When ready for the stitches, I had the chloroform removed, so that it was used only a few minutes, and I was certainly surprised to hear the patient answer a question I put to him a little while later, when he still seemed fast asleep. I found then that he had never been chloroformed at all, but had been in a hypnotic sleep, and he obediently awoke at my command, with a pretty good memory of all that had been said but with no recollection of pain. Since then I have tried this experiment in several instances and lately had a case that afforded ample room for study. I had a patient whom I desired to make somnambulistic in order to have her carry out post-hypnotic suggestions, but I could never produce sleep sufficiently deep, so I used chloroform, which frequently is a great help in such cases, and though it never produced somnambulism in this case, it at least gave me a good opportunity to study the effect of hypnosis and chloroform used together.

From what I have written, it will appear that I agree in the main with Dr. Stoner's explanation and yet I go further and claim that the operation done by Dr. Goldan was not done during chloroform narcosis but during hypnotic sleep.

JOHN R. ROSE, M.D.

EASTMAN, GA., June 22, 1899.

NOTES FROM SWITZERLAND.

[From a Special Correspondent.]

ANOTHER TOTAL EXTIRPATION OF THE STOMACH—INCREASE IN INSANITY IN SWITZERLAND—PROPORTION OF WEAK-MINDED CHILDREN—ILLEGITIMACY—ALCOHOLISM AS A CAUSE OF MORTALITY.

BERNE, SWITZERLAND, June 17, 1899.

ANOTHER case of total extirpation of the stomach for carcinoma of the pylorus remains to be recorded. It was performed by Dr. Kocher in his clinic on Friday, June 9th. The patient was a woman of about forty years of age, very emaciated and with marked cachexia. She had been under treatment for some time on the medical side of the hospital in order to prepare her for operation. Upon opening the abdominal cavity the case was thought favorable for a total removal of the stomach, on account of the absence of lymphatic involvement, so this was done, great care being exercised to save as far as possible all vessels concerned in the nutrition of the large intestine. The stomach was removed as a whole, including the cardia and about 4 cm. of the duodenum. An anastomosis was then made between the esophagus and duodenum and the abdominal wound sutured, leaving a small opening for a glass drainage-tube.

The patient recovered from the operation very well. She was fed per rectum and was seemingly on the high road to recovery until the morning of the third day, when without apparent cause she died. At the autopsy it was found that in spite of the great care during the operation not to interfere with the intestinal circulation, there was a small area of necrosis in the wall of the transverse colon, sufficient to give rise to a mild peritonitis, which was enough in the poor condition of the patient to cause her death. The esophagoduodenal anastomosis was in good condition and partly healed. In all, the patient lived three and one-half days after the operation.

This is really the second case of total extirpation on record. The Zürich case was, strictly speaking, not a total extirpation since part of the cardia was left. Both the San Francisco case and the Berne case proved fatal. The great danger evidently is in the vast circulatory disturbance which is caused in the intestinal tract as well as the interference with the abdominal sympathetics.

Switzerland is indeed a country of antitheses. It contains some of the grandest scenery and health-giving atmospheres in the world, and yet its people are troubled with some of the worst afflictions. Out of a population of a little over 3,000,000, its twenty State insane asylums contain, according to the last report, 6164 inmates, an increase of about 200 over the previous year. Females predominate slightly over males. The cost to the State for the keeping of each person is given as about 250 francs ($48.25) per annum.

There are no laws for the commitment of the insane; no judicial proceedings, such as a trial before a competent court or expert commission, is necessary. All that is needed to commit an individual to an asylum is the certificate of one physician; whether he be an alienist or not makes no difference.

The proportion of weak-minded children is also unusually large. Recent statistics have shown that in all the cantons of Switzerland there were in the primary schools 13,155 weak-minded children. The total number of pupils in the schools at the time the figures were obtained was 463,548, so that in each 1000 there were 16.5 who were in greater or less degree weak-minded. Aside from these, there were 7667 children who were lacking in development in some respect or other. Of these, only 1082 received special attention in special classes.

It is said that one out of every five children born in Switzerland is illegitimate. The reason for this high rate of insanity and defective mental development among children may be looked for in the customs of the people. The Swiss cling to the customs of their ancestors even though the conditions under which their ancestors lived comfortably have changed so as to make their customs impracticable and bad now. The laboring class, including the farmer, works unusully hard, most of the work falling upon the women. The pregnant woman works just the same as the rest, and I have seen women cleaning the streets of Berne who were apparently near full term. The children are also made to work hard. In consequence they are dwarfed and stunted, both physically and mentally.

Alcoholism is getting to be quite an important cause of death in Switzerland, as well as in France and Germany. For the first three months of the past year, namely, from

January 1 to March 31, 1898, there were, between the ages of 40 and 59, 57 men who died from this cause. The total number of deaths among men of this age was 378, so that 15.1 per cent. were due to alcoholism.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

ANOTHER DEATH FROM FAITH-CURE PRACTICES—A CASE OF "SLEEPING SICKNESS" IN PHILADELPHIA—NEW LABORATORIES OF THE MEDICO-CHIRURGICAL COLLEGE—FIFTIETH ANNIVERSARY OF THE NORTHAMPTON COUNTY, PA., MEDICAL SOCIETY—COMMENCEMENT OF THE UNIVERSITY MEDICAL SCHOOL—STATE BOARD EXAMINATIONS—AMERICAN NEUROLOGICAL ASSOCIATION—PERSONAL—VITAL STATISTICS FOR THE WEEK.

PHILADELPHIA, JUNE 26, 1896.

STILL another dupe of the "faith-cure" propaganda has exhibited his belief to a degree incompatible with the continuance of life. This time the victim was a middle-aged and, in other matters, apparently intelligent tradesman, a Mr. Joseph McCraig, who left his home in West Virginia and came to this city to place himself under the instructions and care of a local "faith-curist," William J. Randall, D.C.S. Although this William J. Randall, D.C.S., holds forth in handsomely appointed offices in a prominent office-building in this city, and from external appearances seems to enjoy a very fair degree of prosperity, all this availed Mr. Joseph McCraig nothing, and he died and was properly buried, for he happened to be suffering from an organic heart-lesion, with widespread evidences of compensatory failure. With infantile artlessness William J. Randall, D.C.S., wriggles out of the legal questions involved in Mr. Joseph McCraig's demise. "Christian Science," he remarks, "is teaching the gospel; healing the sick is the smallest part of it. I do not administer drugs. God is the healer. I never say anything about charges. We think that preaching the gospel and healing the sick go hand in hand." He positively denied ever having received money from his late patient, either for reading the gospel or for healing, although he admitted that in other cases the amounts paid to him for "reading," whatever that may indicate, are according to the circumstances of the patient. As it could not be proved that he had prescribed medicines or received a fee for treatment without having the requisite license the coroner turned William J. Randall, D.C.S., loose to browse about on his old stamping-ground, and illegitimately collect money from other dupes possessing more hallucinations than sober judgment.

In view of the present development of general interest in tropical diseases it is not without interest to note that a probable instance of African "sleeping-sickness," or "negro lethargy," occurred in this city during the past week. The patient, a medical missionary, lately returned to this country from Africa, died in one of the city hospitals of an obscure disease contracted in the tropics, and thought to be a genuine case of that fatal malady known as "sleeping-sickness." The patient had spent the last nine years of her life in the Congo Free State, and was attacked eighteen months ago with a characteristic train of symptoms, such as facial edema, progressive wasting and loss of strength, bodily fatigue, torpor, intense apathy, and certain sensory and motor-nerve disturbances. The progress of these symptoms was uninterrupted, even after her return to a temperate climate, and the patient died after an illness of more than a year and a half. Post-mortem examination failed to reveal any typical lesion of the disease in question, but this is not unusual, in view of our limited knowledge of the post-mortem conditions to be sought for. Nor was it possible to demonstrate in the blood embryos of the *filaria perstans*, which form of filariasis, it will be recalled, is conditionally mentioned by Manson as a possible etiological factor in the "sleeping-sickness" common among the negroes of the Congo and of Senegal.

Work has begun on the new clinical laboratories of the Medico-Chirurgical College and Hospital. The design of the building will be a pure example of Grecian architecture; it will have a frontage of 72 feet and a depth of 99 feet, and is to be 5 stories in height, constructed of Pompeiian brick, terra cotta and brown-stone, on a steel skeleton. The first floor is to furnish accommodations for a number of the hospital out-patient departments, a large general lecture-hall will occupy the second floor, and the three upper floors will be devoted to laboratories of chemistry, physiology, anatomy, histology, and pathology. The cost of the new building is estimated at $125,000, and it is proposed to have it completed and equipped for the reception of students by the middle of next October.

The fiftieth anniversary of the Northampton (Pa.) County Medical Society was celebrated June 13th, at Easton. Dr. Amos Seip of Easton, the only survivor of the twenty-two original members of the society read an interesting retrospective address on the history of the society. Addresses were also delivered by Dr. Charles McIntire, the president, Dr. John B. Roberts, representing the Philadelphia County Medical Society, and by Drs. W. Murray Weidman of Reading, and L. H. Taylor of Wilkesbarre, and by prominent representatives of the clergy and bar in this State.

The annual commencement exercises of the Medical Department of the University of Pennsylvania were held June 15th, in the Academy of Music, in conjunction with those of the other departments of this institution. Degrees of Doctor of Medicine were conferred upon 211 graduates of the medical school, and the annual oration was delivered by Hampton L. Carson, Esq. The annual business meeting and banquet of the Society of the Alumni of the Medical Department was held June 14th, and the following officers were elected: President, Dr. Meredith Clymer; vice-presidents, Drs. John H. Packard, James Tyson, S. D. Risley and Charles K. Mills; secretary and treasurer, Dr. S. D. Wadsworth. About 100 members attended the banquet, among those present being Dr. Thomas Dunn English, of the class of '39, famous as the author of the ballad, "Ben Bolt." Speeches were made by prominent members of the faculty of this and other local medical schools.

The examination of applicants for licenses to practise medicine in Pennsylvania began June 20th, simultaneously

in Philadelphia, Harrisburg and Pittsburg, and continued four days. A general average of at least seventy-five per cent. is required to qualify before the three boards, regular, homeopathic, and eclectic; and the candidate must stand examination on the subjects of anatomy, physiology, pathology, practice of medicine, surgery, materia medica, obstetrics, therapeutics, chemistry, diagnosis, and hygiene. The applicants this year numbered 380.

The twenty-fifth annual meeting of the American Neurological Association was held at Atlantic City, N. J., beginning June 13th. Over 200 members were present to listen to the opening address by the president, Dr. James Hendrie Lloyd of Philadelphia.

Among the prominent Philadelphia medical men who sailed for Europe during the present week were Drs. J. William White, W. W. Keen, and G. E. de Schweinitz.

The number of deaths in Philadelphia during the week ending June 24th was 379, a decrease of 44 from the preceding week and of 8 from the corresponding period of last year. Of the total deaths, 122 were of children under five years of age. The following new cases of contagious diseases were reported: Enteric fever, 48 cases, 9 deaths; scarlet fever, 36 cases, 3 deaths; diphtheria, 61 cases, 20 deaths; and cerebrospinal meningitis, 2 cases, 1 death. The total number of contagious diseases reported this week was 57 less than the week preceding.

OUR LONDON LETTER.

MEDICAL COUNCIL AND FOREIGN PRACTITIONERS—PERJURY AT POST-MORTEM—LITERARY AND HISTORICAL MEDICINE—DECISION IN FAVOR OF A PHYSICIAN—DEATH OF DR. NORMAN KERR—ANOTHER AMBULANCE ACCIDENT—"CROSSED APHASIA."

London, June 16, 1899.

The General Medical Council was in busy session all last week under the presidency of Sir William Turner. Several matters of interest and importance were discussed and passed upon, among them two which appeal to the profession outside of Great Britain. One of these was the unexpectedly warm debate which sprang up over the mild suggestion of the Italian Ambassador, transmitted through the Foreign Office, that some sort of reciprocal arrangement should be made for the mutual recognition of English medical degrees in Italy and Italian degrees in England. English medical men have long bitterly complained of the hardship of being obliged to secure the local degree before they are permitted to practise in Italy, where, of course, wealthy invalids of all nations swarm in colonies, and the committee to which it was first referred therefore hailed it as a joyful omen and reported favorably upon it. The storm of indignant protest that burst upon the committee evidently astonished it. "It is the thin end of the wedge;" "if we make this concession to Italy we shall be obliged to extend it to Austria, Spain, the whole of Europe, even the United States;" "what is the use of laboriously building up a high standard of medical education, and then throwing open the flood-gates to the riff-raff of the medical world?" and like frenzied appeals poured in thick and fast. And the finishing touch was given when the supporters of the proposal only ventured to do so on the ground of humanity toward English travelers falling ill in Italy, who might suffer severely if they were obliged to depend solely upon the incompetent ministrations of the average ignorant practitioner of that benighted land.

Altogether the debate was hardly creditable to either the breath of view or the courtesy of the English Medical Senate, although it is quite probable that having relieved their minds and expressed their insular contempt and scorn for "Eyetalians" and "furriners" in general (who may also perchance have had some small struggle of their own for a higher standard) their sense of fair play will assert itself and they will proceed to practically grant the concessions asked for—and then wonder why the foreigner aforesaid is not both grateful and affectionate.

The other matter is the last act in that curious drama of alleged perjury in a post-mortem report, which was described in a former letter. A certain Dr. MacKay was ordered by the coroner to make an autopsy upon a child that had died suddenly. He did so and reported that death had been due to cerebral congestion, but the coroner was for some reason suspicious and ordered a second examination made by the district police-surgeon and another physician, who reported that the skull had not even been opened and that death was due to pneumonia. Whereupon Dr. MacKay was committed on a charge of perjury, but the judge before whom it was tried chose to regard it in the astonishing light of an ordinary "doctors differ" and dismissed the case. The mills of the gods were still grinding, however, and last Tuesday the grist was delivered, after a hearing in person before the full council, in the shape of an order to strike Dr. MacKay's name from the Register, which deprived him of the right to practise in Great Britain. If the executive committees of some of our great national bodies only possessed this right of disciplining gross breaches of professional duty and honor what a bracing effect it would have on our medical atmosphere!

The medical faculty of Cambridge has reconsidered its decision not to hold the usual vacation course in pathology, on account of the death of Professor Kanthack, and announces the course to begin July 6th and to continue six weeks under the charge of Professor Sims Woodhead and G. Strangeways Pigg.

June 11th, was "Hospital Sunday," when most of the pulpits in London had hospital sermons preached from them; followed by a collection for this great charity. The *Lancet* has issued its annual Hospital Supplement, giving an admirably clear statement of the purposes for which these funds are urgently needed in future and the uses which have been made of them in the past.

One aspect of the literary activities of our English brethren is distinctive and worthy of imitation, and that is the prominence which is given in their society proceedings to the literary and historical aspects of medicine. Two papers of this character have been read before prom-

inent medical bodies during the past few weeks, one by Mr. Albert Doran, on "The Medicine of Shakespeare's Time, as Presented in His Writings," a witty and most ingenious piece of work, consisting chiefly of one continuous stream of "quotations in solution," as Charles Lamb called them. The other was an address by Dr. Vivian Poore, on "English Medicine in the Eighteenth Century," a most entertaining sketch of our fathers in medicine, their personalities as well as their work. A capital story is related of the famous Radcliffe, court-physician to Anne and William III., but celebrated for his most uncourtly manners. The king, who was suffering from dropsy, called him in and showing him his swollen legs asked him what he thought of them. The soothing answer was jerked back: "I would not have your Majesty's two legs for your three kingdoms." He was not called again to that case. It was Radcliffe who founded the great Radcliffe Library at Oxford, although it was his boast for a long time before his death that he had not read a book for thirty years. Indeed, a wit of the time declared that for Radcliffe to leave his fortune to found a library was like a eunuch endowing a harem.

A case of some interest to physicians has just been decided in the courts. A clergyman refused to pay a bill of $35 for services rendered to his wife, mother, and son, on the ground that the doctor had not used "modern scientific methods of examination" and make a mistake in diagnosis. On taking one of the patients to Germany this mistake was set right and a cure promptly followed. We have all met just that variety of cleric and it is a comfort to know that an unabashed judge ordered him to pay the account on the ground that the fact of his deliberately choosing Dr. Collins and putting him in charge of the cases implied confidence in his skill and rendered him liable for all reasonable fees until formal dismissal was made. Why is it that the class which pays the least, often indeed no fee at all, is always the readiest to turn against us and consult a quack?

Dr. Norman Kerr, the well-known specialist in inebriety and medical temperance reformer, died May 30th, at his home in Hastings. He was the author of more than twenty works on inebriety and kindred subjects, and probably did more to promote rational temperance and the medical treatment of inebriety than any other man of his time. We in America remember him gratefully as the man who prevented the Keeley "gold-cure" swindle from getting a foothold in England, by quietly suggesting to the Government that Keeley should be required to give a demonstration of the value of his method before a committee of the Society for the Prevention of Inebriety, upon patients furnished by it, a test which the wily promoter of course dared not submit to, and by his refusal stamped himself as a charlatan, so that the authorities promptly declined to grant any permit for the opening of his institutions.

A dinner was given to Sir William MacCormac last week by all the house-surgeons who had been under him at St. Thomas' Hospital during his twenty years of service. No less than seventy-seven of them were present at the banquet.

It has long been noticed what a curious tendency rare cases have to occur in pairs or trios, and the same seems to apply to accidents. Only last week we reported a death in an ambulance, due to reckless driving, and this week comes the news of a similar accident at Liverpool. A man who had been injured in a street-accident was being taken to the hospital in an ambulance, when the horse took fright, ran away and collided with a lamp-post, and the patient was picked up dead. This time no blame was attached to the driver, but rather to the horse, which had only one eye and was known as a "shyer." So the coroner's jury passed a solemn vote of censure on the contractor for furnishing such a horse for ambulance purposes, and there the matter rested again.

Dr. Byrom Bramwell has recently reported a unique case of "crossed aphasia" or loss of speech following a lesion of the *left* cortex, in a left-handed person, showing that the speech-center is not always situated on the right side of the brain in such individuals, although such is the general rule. He also confirms Collins' interesting observation, that if the destruction of Broca's convolution be sufficiently gradual, aphasia does not follow, which he regards as due to the gradual "education" of the corresponding center on the other side of the brain.

The Government Commission on Food and Drugs is now considering measures for the stringent regulation of the use of preservatives in foods. It has been discovered that both fresh fish and meat often possess a slight but very persistent bitter taste, traceable to the use of formalin. This, though not poisonous, is highly objectionable on account of its hardening effect on the proteids, especially when used in milk, rendering them difficult of digestion.

TREATMENT OF GUN-SHOT WOUNDS OF THE CHEST—EFFECTS OF RESECTION OF THE CERVICAL SYMPATHETIC NERVE—OCULAR MASSAGE—CURE OF HEPATIC HYDATID CYSTS—SUTURE OF A FRACTURED CLAVICLE—AN INCOMPLETE OPERATION FOR SINUS THROMBOSIS—OPINIONS ON THE BEST TREATMENT OF HEMORRHOIDS—RUPTURE OF THE THREE PARTS OF THE QUADRICEPS AT DIFFERENT PLANES—SUTURE OF THE AXILLARY ARTERY—WARM BATHS IN MENINGITIS COMPLICATING PNEUMONIA—WHEN MILK ACTS AS A POISON IN UREMIA—MISTAKE IN X-RAY DIAGNOSIS.

AT the Academy of Medicine, May 16, LUCAS-CHAMPIONNIERE showed a man who two months previously had received a bullet in his chest. The ball had entered at the right side of the upper part of the sternum, and the direction of the wound indicated that it had passed through the right lung. There was expectoration of blood, and marked collapse. The patient was kept absolutely quiet, and the external wound was cleansed. Further than this, nothing was done, although the following day there were signs of a large effusion of blood into the right side of the chest. The patient recovered satisfactorily, and a radiograph showed that the bullet was situated near the twelfth rib. The speaker took the opportunity to em-

phasize the importance of absolute rest in the treatment of such cases. In abdominal wounds early surgical interference is demanded. In wounds of the chest, the reverse is true, and the patient should not even be turned over for the purposes of auscultation. He should be kept horizontal, or slightly inclined if respiration is facilitated thereby, and morphin should be given to allay restlessness, and laxatives and, if necessary, stimulants.

At the meeting of May 23d, FRANCOIS-FRANK spoke of the effect of the division of the cervical sympathetic nerve upon the circulation of the thyroid gland, the brain, the eyes, and upon the heart. It is logical to believe, that the resection of the sympathetic acts at least as much to suppress the transmission of abnormal excitation of a cardiac or aortic origin toward the center as it does to suppress the centrifugal influences of the thyroid, brain or heart. Irritations of the cardiac and aortic fibers, as of all the fibers of the sympathetic, may produce circulatory changes which suggest the attack in Graves' disease, including thyroid vasodilatation. Consequently the total resection of the sympathetic can easily produce good results, especially in cases marked by reflex disturbances of aortic origin.

DARIER said that ocular massage had proved of such benefit in stimulating the accommodation of hypermetropic patients, that several of those so treated had been able to lay aside their glasses. In hypermetropic strabismus, the amblyopic eye had been so improved that binocular vision had become possible, thus aiding in the cure of the strabismus. The acuteness of vision of several myopic patients was increased, but the eyes themselves were not altered. In a certain number of cases of glaucoma the sight had also been improved by massage.

At the session of May 30th, DIEULAFOY spoke of two patients whom he had permanently cured of hydatid cysts of the liver; the first, a man, by means of a laparotomy and extirpation of the cyst; and the second, a child of ten years, by aspiration of the cyst contents. He spoke of the relative merits of these two procedures. Puncture is only suitable for recent cases, and should be done with every precaution to prevent the escape of fluid into the peritoneal cavity. To this end a fine needle should be used, and the whole of the contents of the cyst should be drawn off at the first puncture. If the needle clogs before this end is accomplished, a second needle should be introduced, without disturbing the first, and the two withdrawn at the same time.

At the Surgical Society, May 10th, SIEUR said that he had resected the ununited ends of a clavicle, and sutured them together with two threads of silk. The fracture was of eight-months' duration and separated the outer third of the bone from the inner two-thirds. After the suture the arm was fixed for a month. In sixteen months after the suture every trace of the fracture had disappeared and the function of the arm was perfectly restored.

BROCA discussed a case of mastoid abscess which had been treated by DELANGLADE. He had opened the mastoid cells and then an extradural abscess, and believed that he had gotten beyond the trouble until the signs of sinus phlebitis appeared on the following day. The lateral sinus was therefore exposed but not opened, neither was the jugular tied. After a secondary femoral osteomyelitis the patient recovered. Broca thought that the ligature of the jugular and the opening of the sinus would have saved the patient from this complication.

At the session of May 17th, there was a discussion of the treatment of hemorrhoids, which was interesting as showing the very different opinions held by well known surgeons in regard to the treatment of this most common disorder.

MONOD, operating under chloroform, does not touch the external hemorrhoids and cuts off the internal ones, one at a time, with scissors, suturing immediately the cut mucous edges of each. A drain wrapped with iodoform gauze is left in the anus.

RECLUS uses cocain and thinks it important to remove the external as well as the internal hemorrhoids.

POZZI said that it is advisable to respect, as much as possible, the mucous membrane. He, therefore, employs only ignipuncture in the treatment of hemorrhoids.

TILLAUX also uses the thermocautery in the same manner. He said that its only inconvenience is the pain which lasts sometimes for two or three days after its use.

QUENU advocated general anesthesia in order to keep the rectum of the patient still. Under cocain it is drawn up involuntarily, even though no pain be felt. He said that different operations were indicated in different cases. If hemorrhoids are particularly turgid, ignipuncture is a better treatment than excision. Prolapse of the mucous membrane is a common complication which cannot be cured by the cautery nor by partial excision. Ignipuncture gives eschars, which do not come away for twelve or fifteen days, and its one advantage is in the economy of blood. The sole objection to Whitehead's operation is the difficulty in carrying it out properly; but that will disappear if the surgeon will accustom himself to its details. It is not followed by pain, and cicatrization is complete in two weeks. He had never seen any contractions follow this operation.

ROUTIER said that there would be no danger of retraction if the line of junction of mucous membrane and skin was respected. His plan is to ligate each hemorrhoid at its base, and then remove the projecting portion with a thermocautery.

POIRIER described a case of rupture of the quadriceps tendon, in which the three different tendons of which the whole is composed were separated at different levels. The tendon was sutured, with a perfect result. As the end of the crural portion was interposed between the ends of the right anterior portion, the result by massage would have been inferior to that obtained by operation.

May 24th, RICARD spoke of the suture of the axillary artery which he performed in the course of an operation for the removal of the axillary glands. The axillary vein was resected for a considerable distance, and the artery was accidentally incised. A lateral suture of catgut was applied at four places. The result was apparently perfect, there being no difference in the radial pulse of the two arms.

TUFFIER said that in his experiments on animals, suture of an artery was usually followed by a callous which so compressed the vessel as to make it impervious.

BAZY said that he had resected five inches of the axillary artery with no ill effects, so that he considered its suture unnecessary in such a case as the one under consideration.

At the Medical Society of the Hospitals, May 12th, RENDU described a case of pneumonia complicated with meningitis occurring in a girl aged five years. Cold baths were used in the treatment and the patient was recovering from the pneumonia when she developed the symptoms of meningitis, stiffness of the neck, contraction of the muscles of the jaws and limbs, elevation of the temperature, etc. Warm baths were substituted for the cold ones, and 100 c.c. of saline solution was injected daily. Calomel and bromid of potash were given in small doses. Under this treatment the child slowly recovered her health.

May 19th, RENON said that he had found that a milk diet acted as a poison in certain cases of uremia, just as it did in certain cases of enterocolitis, and probably for the same reason. The diet, therefore, ought to be the same as that recognized as best in the latter trouble. In five cases where he had carried out this plan of treatment, giving rice water and bean soup without meat for several days, vomiting, diarrhea, and dyspnea had disappeared, and the albumin in the urine had been reduced to almost nothing. Later a leguminous and farinaceous diet was given, and after that a milk diet, a mixed diet being withheld until all danger had passed.

At the session of May 26th, BECLERE gave the results of an autopsy which illustrated the care which must be used in drawing conclusions from X-ray examinations of the abdomen. His patient was supposed to have a subphrenic abscess, containing air, but the air-space was found to be a displaced transverse colon, while the pain was due to pleurisy, and the enormous purulent expectoration, which was thought to indicate a connection between the subphrenic abscess and the bronchi, came from the dilated bronchi of the right lung. A previous pneumonia had apparently been the origin of the whole trouble.

SOCIETY PROCEEDINGS.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Abstract of the Proceedings of the Twenty-first Annual Meeting, Held at Chicago, Illinois, May 22, 23, and 24, 1899.

FIRST DAY—MAY 22D.

THE Association met in the rooms of the Chicago Medical Society, and was called to order by the President, DR. WILLIAM E. CASSELBERRY, who delivered an address. He said that the honored custom of an address from the chair affords opportunities for suggestion looking to the welfare of an organization and of the department of medicine which it represents which would not find expression in any set paper or formal discussion. All are conscious of the change in the drift of laryngological practice during recent years, first, by the evolution of nasal pathology, and second, by the appropriation of the ear. From a physician treating affections of the throat and chest, the laryngologist is fast becoming a surgeon with a routine of practice limited to local measures as applicable to the upper respiratory tract alone. While freely conceding that progress has been realized along surgical lines, he deprecated the tendency of the day to deal with the throat and nose exclusively in a mechanical way, as if they were organs detached. He believes it engenders narrowness of thought, and that, through habitual disuse, there is gradually lost to the physician much of that fundamental knowledge of pathology and applied therapeutics which is so essential to the welfare of the patient.

Do latter-day laryngologists, as a class, habitually endeavor to establish the real diagnosis in the earliest demonstrable stage of pulmonary tuberculosis? Are not such patients liable to come first before us with their irritable throats, hacking cough, tendency to hoarseness, and inclination to rhinitis? It is not claimed that the laryngologist must of necessity embrace in his practice all pulmonary disease; that is a matter of choice, and expediency, but it is urged that he be ready to apply all the arts of diagnosis, and that he be conversant with every resource known to medicine in the treatment of pulmonary conditions for the benefit of cases of laryngopulmonary tuberculosis, laryngobronchitis, bronchial asthma in association with ethmoiditis, and other conjoined pathological conditions of the upper and lower respiratory tracts. Nor will it answer to omit attention to the heart, aorta, and mediastinal contents. Paralysis of a vocal cord through pressure on the recurrent nerve by an aneurism is a simple proposition, but more complicated ones which require a high degree of diagnostic skill are continually encountered.

Regarding the treatment of pulmonary conditions, especially tuberculosis, cases which are not complicated by affections of the throat are naturally claimed by the department of internal medicine. It is not possible, nor even desirable, to draw an absolute line at this point between laryngology and internal medicine; in practice they are bound to overlap, but conceding that if drawn anywhere it would be here, there remains a considerable proportion of pulmonary cases in which the upper respiratory tract is so far implicated that they fall naturally under the care of the laryngologist. Hence, as before said, he should be conversant with every resource known to medicine in the treatment of pulmonary states. He should be a good systemic therapeutist, and continue to cultivate the art of prescribing, realizing the uses as well as the limitations and abuses of internal medication. Above all, one should study the conditions of natural immunity and susceptibility in order that having made an early diagnosis, one may direct the mode of life and place of abode best adapted to arrest the disease and overcome the susceptibility. This implies a ready familiarity with sanitation, hydrotherapy, climatology, and sanatorium resources and methods.

All laryngologists are familiar with the many throat conditions which appear as salient features of underlying

systemic states, and yet in the overswing of the movement toward localism general pathological data, systemic therapeutics and hygienic aids are not always utilized to the utmost. How often is edema of the larynx merely secondary to chronic nephritis; and laryngeal ictus simply the forerunner of locomotor ataxia?

Dr. John W. Farlow of Boston read a paper, entitled "Is the So-Called American Voice Due to Catarrhal or Other Pathological Conditions of the Nose?" He said that the so-called American voice is so often referred to that he thinks we are justified in making inquiry as to its nature and cause. Liability to nasal catarrh is considered to be the determining cause. Laryngologists are all agreed that it is the exaggerated nasal quality, the production of voice in the nose, the twang, which is its most notable characteristic, and a consideration of the larynx and fauces as factors can be omitted. It is not the thick, muffled voice of weak carrying power, such as occurs in cold in the head, but the high, penetrating, vibrating voice, indicating an openness of the nasal chamber, so that the voice made in the larynx finds its way into the nose. Any condition which hinders the passage of air into the nose, such as large tonsils, adenoid disease, post-nasal polypi, or tumors, enlargement of the posterior ends of the turbinals, tends to diminish the nasal resonance, and hence should not be considered as contributing to the production of a nasal voice. When we say we talk through the nose, we mean that we do not speak *through* but *in* the nose, and we may distinguish between the sound made when only the very anterior part of the nose is obstructed, as when the nostrils are closed by the fingers, and when the obstruction involves the turbinals, as in acute coryza, the former sound approximating more the nasal twang.

The essayist then considered the effect of chronic catarrhal conditions of the mucous membrane of the nose without hypertrophy, so often associated with a similar disease of the post-nasal space. In severe cases of long standing there may be anesthesia and paresis of the soft palate, which would diminish the proper activity of the muscles which shut off the fauces from the post-nasal space, and thus some of the tones which should be made in the mouth are involuntarily formed higher in the nose and acquire a nasal character. This is well known to occur temporarily immediately after the removal of a large adenoid before the palate has regained its proper strength. Apart from the effect of the incomplete movement of the palate, the author does not see that an atrophic condition of the nose tends to make a nasal voice if the method of speaking is correct. If it is incorrect the nasal character should be more marked owing to the greater opportunity for vibration.

For purposes of study he divided patients roughly, according to age, into, first, children up to twelve years; second, those from twelve to thirty years old, and third, those above thirty. There can be no question that the nasal voice is very common in the first class. The voices of young children at play or in the class-room are often very noticeable for their nasal quality. From twelve to thirty years of age there is an increase in the number of cases of obstructing septa and anterior turbinal hypertrophy. Polypi are more common, and atrophic rhinitis with some paresis of the palate is also more frequent. He should say that the nasal voice is met with very often at this age, but not more frequently than in the preceding period, and certainly not proportionately to the increase in causative conditions. After thirty years of age the various pathological conditions continue, and the sclerosing inflammations of the mucous membrane become more marked. As to the frequency of the nasal voice, his impression is that it is rather less common than earlier in life, perhaps in the sense that there is a larger proportion of voices with no nasal intonation, although there are many very marked examples of the nasal twang, while in the young the number who speak without any nasal twang is decidedly less.

If the opinion is correct that the condition of the nose is not the principal factor in causing the faulty voice, physicians should certainly expect to be able in many cases to improve the manner of speaking without medical or surgical treatment of the nose. Many excellent singers have throats and noses which are far from normal, and pathological conditions have more to do with the range and power of endurance of the singing voice than with its proper quality in the medium registers, and when used in moderation.

He believes that anterior nasal obstructions are common in all civilized races, and that there is no reason for thinking that any peculiarity in the American voice is due to what is possessed by others equally with ourselves. The parts of our country, where are the oldest centers of civilization and education, should be the places where most attention is paid to both the singing and the speaking voice, and this is probably the case, but in our old country villages distant from the populous centers the voices of the natives are well known to have the nasal twang without regard to the condition of the inside of their noses.

Dr. James E. Newcomb of New York City read a paper on "Adenocarcinoma of the Nose," in which he reported the following case: Mrs. C. C., aged sixty-one years, widow, of American parentage, was referred to him on account of severe and persistent nosebleed. Her family history was negative, and her previous history was without apparent bearing on her condition when seen. In June, 1898, she began to have almost daily bleeding from the left naris. She had been subject for many years to severe colds in the head, and was inclined to attribute her troublesome symptom in some way to this fact. The bleeding always stopped of its own accord, and no operative interference had ever been necessary. On two occasions it had been quite severe, but on all others it had been a mere dribbling. In September she had blown from the nose what she described as a "fleshy bean," and which was in all probability a polyp of usual variety. She had lost some flesh and strength during the few preceding months, but no more than could be accounted for by the continual though slight bleeding. At times there had been a slight watery discharge with an offensive odor. None was present at the time of examination. The lat-

ter showed a woman of large frame, but with a rather worn and debilitated appearance. Pharynx, naso-pharynx, and larynx presented nothing especially noteworthy. The right naris showed commencing senile changes. The left was considerably occluded. The middle turbinate was considerably enlarged, and the mucosa covering it appeared to be in a condition of polypoid degeneration. About it were two or three fleshy proliferations which bled rather easily upon manipulation with the probe. No granular enlargement could be found, and there were no manifestations of pressure symptoms. Under ten per cent. cocain a portion of one of the fleshy masses was removed and sent to Dr. Wright for examination. His report was adenocarcinoma. Removal was followed by a little more bleeding than is the case with an ordinary polyp, but was easily checked, and there was no unpleasant reaction.

The patient was seen again in two or three weeks, when it was noticed that the mass had reproduced itself in the same situation. A second piece was removed as before. There had been no bleeding in the meantime. The report upon the second piece was to the effect that it consisted of edematous tissue, with some newly formed and perfectly granular structures, all of it granular and degenerate-looking, nothing definitely malignant, but certainly suspicious. Patient was seen again for the third time on March 13th of the present year. The same reproduction of tissue was noted as before, but none was removed at this time. There had been two spontaneous hemorrhages during the week preceding this visit, one of them quite severe.

The patient was made acquainted with the gravity of the situation, and the question of a radical operation was submitted fairly to her. Thus far she has been unwilling to undergo the ordeal. She was last seen early in the present month (May, 1899). During the last few weeks the daily dribbling hemorrhages have continued and at times there has been a perceptible offensive odor. The occlusion of the nostrils is gradually increasing. Her general condition seems to be about the same as before.

With this case the author mentioned six cases to be added to those enumerated in a table prepared by Dr. Hopkins.

As to surgical measures, up to the present time two general operative procedures have been followed: first, removal of the superior maxilla, with more or less of the surrounding structures; second, attempted starvation of the growth by cutting off its blood-supply. In pursuance of the latter end the external carotid has been ligated. He has been interested to learn of a modification of this procedure, first made by Dr. Dawbarn. He found, upon studying the anastomotic circulation, that after simple ligation of the external carotid there were fully twenty channels, through which collateral circulation could be established. With a view, therefore, of still further cutting off the blood-supply, he conceived the idea of ligating, one after another, the eight branches of the external carotid, and then, as the trunk of the vessel was thus rendered useless, of resecting it entire. He has performed this operation sixteen times upon eight patients, a two-weeks' interval elapsing between the two operations in each case. It has been performed once or twice by others. While the period covered by this work is too short, and the number of patients thus operated upon too few to allow of decisive conclusions, the author believes that time will demonstrate the logic and effectiveness of this operative modification.

DR. A. COOLIDGE, JR., of Boston followed with a paper, entitled "Removal of a Foreign Body from the Bronchial Tube Through a Tracheal Opening," and reported a case. The report illustrated the ease with which a foreign body can be removed from a bronchus. Patient, male, aged twenty-three years. He had worn a tracheotomy tube for twenty years on account of stenosis of the larynx. His last tube was made of hard rubber, and was several months old. Twelve hours before admission the tracheal tube had become detached from the shield, and had been inhaled, causing severe coughing, and distressed and noisy breathing, which, although less severe, was still present when he was admitted. Examination by X-ray was negative. Patient was etherized, put on his back, with the shoulders over the end of the table, and the head held downward and rotated to the right side. The tracheal opening was enlarged downward. Not having any other straight tube of proper caliber on hand, the essayist used a urethroscope, half an inch in diameter, and three inches long, a little short for perfect examination. This was passed through the tracheal wound with the stylet in place, turned down, the stylet withdrawn, and the speculum without any difficulty pushed down the trachea to within about an inch of the bifurcation. For illumination a head mirror and reflected sunlight were used, and this illuminated the field perfectly. The foreign body was seen in the right bronchus, the upper end about one-half an inch below the bifurcation. It was seized with a long pair of alligator forceps introduced through the speculum, and removed without difficulty. The patient suffered no ill-effects from the operation. During the whole time respiration was carried on easily through the speculum, except in attempts at coughing at first, which soon subsided. There was no inconvenience from secretion.

DR. G. HUDSON MAKUEN of Philadelphia reported an interesting case of stammering, exhibited the patient, and demonstrated the methods employed in treatment.

DR. M. R. WARD of Pittsburg read a paper on "Septic Thrombophlebitis as a Complication of Peritonsillar Abscess," and reported two cases.

Peritonsillar abscess, or quinsy, is a common throat affection, and while the natural tendency is for the disease to run a favorable course, his personal experience, together with a study of the literature on the subject, has impressed him with the possible fatal complications that may arise in any case, and of the necessity of a more guarded prognosis. Bosworth has given by far the most complete account of the rare complications of this disease. He inclines to the belief that the most frequent fatal complication is rupture of the abscess during sleep, the pus entering the air passages, producing death by asphyxia. The literature, however, would indicate that

hemorrhage is the more common fatal complication, and that septic thrombosis, or thrombophlebitis is exceedingly rare.

It is the exception rather than the rule for the specialist to be called upon to treat a case of peritonsillar abscess, or quinsy. This disease, by custom, belongs almost exclusively to the domain of the general practitioner, while the treatment, if instituted at all, is purely symptomatic. Surgical interference is condemned as extra hazardous; medical as inefficient, and the patient is usually dismissed with the comforting remark, that "the abscess will rupture in a few days, when his sufferings will be at an end." This is usually true, but occasionally a pneumonia intervenes, when the physician is again summoned, and the disease then receives the full measure of his attention and skill. The patient dies, and the death certificate reads "death from pneumonia." The peritonsillar abscess has been entirely overlooked as an etiological factor in causing the death of the patient.

The evolution of sinus thrombosis, cerebral and cerebellar abscess as a result of mastoid suppuration, has been slow but sure. To-day the aurist and neurologist are fully alive to the possibility of such complications, and the condition is not an infrequent occurrence. An infective process in any portion of the body is liable to produce a general infection. This takes place either through the lymph or blood channels. When the infection is conveyed through the blood channels, we generally have to deal primarily with the thrombosis or thrombophlebitis. The thrombus is usually found in the veins in close proximity to the seat of the primary infection, though not necessarily so.

The conditions favorable to thrombosis are alterations in the blood current, changes in the vessel walls, and alterations in the blood itself. Any one or all of these conditions may be present in a given case. The slowing of the blood current from narrowing of the vessel by pressure from the inflammatory products without predisposes to the formation of thrombi.

The number of published reports of cases of infective thrombosis, or thrombophlebitis, as a complication of peritonsillar abscess is exceedingly few. Bosworth, in his exhaustive treatise on diseases of the nose and throat, devotes a paragraph of five lines to this rare complication, and refers to cases having been reported by Rigal, Didelot and Kiemann. A careful review of the literature at the author's command adds nothing to the list referred to by Bosworth.

The author then detailed two cases that had come under his observation. The paper served to show not only the possibility but the serious nature of thrombophlebitis as a complication of peritonsillar abscess, and of the necessity of a more guarded prognosis in the treatment of this disease.

DR. THOMAS HUBBARD of Toledo, Ohio, followed with a paper, entitled "Report of Cases of Peritonsillar Abscess Associated with Diphtheria." In cases of diphtheria of the mixed-infection type the initial inflammatory reaction of the tissues of the throat and lymphatic system is frequently such as to lead us to expect deep suppuration or peritonsillar abscess. There is frequently undetected superficial pus-formation along with coagulation necrosis, but peritonsillar abscess is a rare complication of diphtheria. Two cases exhibiting both diphtheria and quinsy at the same time came under his observation within a year; the more interesting of the two we give below. The case presented a general clinical history that very clearly demonstrated the vagaries of mixed infection, two different members of the family exhibiting types of infection ranging from simple sore throat to abscess and fatal diphtheria.

The eldest son of a large family had sore throat and remained at home for a few days. Two younger children had attacks of mild tonsillitis, as described by the mother. No physician was called. A few days later a younger daughter developed typical diphtheria, and another had quinsy. About four days later the one was moribund from diphtheritic toxemia, and the other had a large peritonsillar abscess, with pseudomembrane over most of the throat. The abscess was incised and a large quantity of pus evacuated. The diphtheritic patient died within an hour of his first visit. The other received 4000 units of antitoxin and recovered after a very severe sickness. A baby sister developed diphtheria of the most virulent type and died within two days of the diagnosis.

This series of cases of mixed infection suggests that the virulence of the different bacteria, together with the age and natural resisting power of the patient, determines which type, false or true diphtheria, or peritonsillitis, shall predominate. In cases of this character, where pus is confined beneath tissue covered with a diphtheritic membrane, the question as to the propriety of early incision is an important one. The more that the surface is abraded the deeper will the diphtheritic infection penetrate and the greater be the absorption of toxins. We should be guided by ordinary surgical principles, and first locate the pus accurately. It should be evacuated only through tissue already devitalized by softening, and vascular tissue should be avoided if possible.

The Association discussed in a symposium the relation of pathological conditions of the ethmoid region of the nose to asthma. DR. HENRY L. SWAIN of New Haven, Conn., dwelt upon the pathology. He stated that an accepted theory is that there must be, first, an irritability of the bronchial structures which makes possible the explosion of energy known as asthma. This hyperesthetic condition is frequently the result of disease, and the multiplied and oft-repeated attacks always induce disease, and consequently greater irritability. Secondly, we usually find some other structure is diseased or oversensitive. An irritation or disturbance of it sets into motion the spasm of the bronchial apparatus. Thus we find that one asthmatic has an irritable nose, another a stomach, another a kidney, or an ovary, and if to these vulnerable organs certain stimuli are applied an explosion results. But to connect the nose, stomach, or kidney with the bronchial tubes a third element must be brought in, namely, the vasomotor system, or, as it is more often put, the neurotic habit.

The author is inclined to believe that lesions of the ethmoid, or generally speaking middle turbinate region, are of an edematous nature. How rarely, if ever, does one see a case of genuine atrophic rhinitis with asthma? The lesions are, therefore, hypertrophic in character, and at first confined to the mucous membrane. In more than sixty cases purulent ethmoid disease has only existed three times, and in these it was secondary to long previous existence of edematous tissue. Marked disease of the bony structures occurred in these sixty cases some six or eight times without purulent conditions, and was here also due to inveterate formation of polypi, which latter the author is led to believe is always the rule, namely, that the disease of the mucous membrane precedes that of the bone. Septal spurs and bends seem to keep up middle turbinate disease and increase the possibility of pressure, which seems in a great many cases to explain asthma. But in all, whether complicated or not, there was hypertrophic disease always present, and usually of the edematous type. Very often these edematous hypertrophies were polypoid in form. We have merely to explain the production of hypertrophies, edematous and otherwise, in these cases, to have the pathology of nasal lesions clearly discussed. When treating many of the pathological conditions in the nose, whether asthma exists or not, the physician must often look outside of the nose, and many times outside of the body, for the causes which have led up to them.

DR. E. FLETCHER INGALS of Chicago discussed the clinical phases. He has seen cases of asthma relieved quite promptly by the removal of polypi, the patients gradually improving for days or weeks without having any asthmatic attacks, until the polypi recurred. He mentioned one patient who was peculiarly unfortunate in that he was a teamster, and whenever he went near the stable he had asthma. He had known patients who could drive on a dusty road behind oxen without having attacks of asthma, yet who could not ride behind horses without having it. He mentioned other patients who could ride bicycles no matter how much dust there was, but who could not ride behind horses. He cited the cases of one or two patients who assured him they had asthma on one side only.

DR. F. H. BOSWORTH of New York, in speaking of the treatment, said there can be no question but that edematous hypertrophy, polypoid degeneration and polypi in the nose are intimately associated with asthma, and the removal of these pathological conditions would relieve the attacks of asthma temporarily, or in some cases, perhaps permanently. Clinical observation teaches us this. He contends, and has for a number of years, that we can go further than this and say that ethmoiditis is an etiologic factor in asthma. Oftentimes asthma is relieved temporarily by the removal of polypi, then it recurs. Why? Because the physician fails to recognize that nasal polypi are only symptoms, or manifestations, of the disease in the ethmoid cells, and in removing simply the polypi he has not clearly carried out the clinical indications. More radical operative measures are necessary to effect a cure of asthma.

DR. F. E. HOPKINS of Springfield, Mass., read a paper, entitled "Recurrence of the Tonsil after Excision," and reported a case. A careful search of the literature of the subject discloses several cases, but a wide variety of opinion is represented as to the frequency and cause of recurrence, as well as of its prevention. It is noticeable that few cases are alluded to by laryngologists, and that most of the references are of cases which were published some years ago. The inference is that under general anesthesia, now so commonly employed, a more thorough operation is performed and recurrences must be even more rare than formerly. Among the causes of recurrence, aside from imperfect operation, are a tubercular or specific dyscrasia, and an acute inflammation of the stump. This acute inflammation of the stump must take place soon after operation in order to result in recrudescence of the tonsils, as occurred in his own case; yet Mackenzie mentions a recurrence following acute inflammation long after operation.

DR. E. FLETCHER INGALS of Chicago reported a case of fibrolipoma of the epiglottis and base of the tongue, and exhibited the patient.

DR. D. BRADEN KYLE of Philadelphia reported a case of confined suppuration of the frontal sinus with spontaneous rupture; and Dr. John O. Roe of Rochester, N. Y., followed with remarks on the presence of partitions and diverticula as a cause of retarded recovery in the treatment of diseases of the maxillary antrum.

The following officers were elected for the ensuing year: President, Dr. Samuel Johnson of Baltimore; vice-presidents, Drs. T. A. DeBlois of Boston, and Moreau R. Brown of Chicago: secretary and treasurer, Dr. Henry L. Swain of New Haven, Conn.; librarian, Dr. J. H. Bryan of Washington, D. C.; member of the Council, Dr. William E. Casselberry of Chicago. Place of meeting, Washington, D. C., in conjunction with the Congress of American Physicians and Surgeons, May, 1900.

REVIEWS.

DEFECTIVE EYESIGHT. THE PRINCIPLES OF ITS RELIEF BY GLASSES. By D. B. ST. JOHN ROOSA, M.D., LL.D., Professor Emeritus of Diseases of the Eye, New York Post-Graduate Medical School and Hospital; Surgeon to the Manhattan Eye and Ear Hospital, etc. New York: The MacMillan Company, 1899.

SOME years ago there appeared, in a series by various authors upon different subjects in medicine and surgery, a little book by the author of this volume, entitled "The Determination of the Necessity for Wearing Glasses." This now appears under a title which better explains its object, very much enlarged, illustrated, and almost completely rewritten, so thorough has been the revision made necessary by advance in knowledge of the proper prescription of glasses, especially in regard to simplicity and accuracy. The manual will be found a reliable guide to the student as well as to the practitioner in ophthalmology, while the easy, almost colloquial style and system-

atic arrangement of topics will add to its interest to those educated people and general practitioners who, without having a special interest in the subject, wish to know the principles upon which the prescription of glasses is based, and who will find with these a number of interesting cases from the records of an authority, and the illuminating critique of an eminent ophthalmologist. The author's standpoint on muscular insufficiences may appear extremely conservative. He says: "It has been reserved for our time to produce those, of whom the present author is one, who . . . have ceased to believe in the existence of any such condition as 'muscular asthenopia.'" While this may seem to go too far, it is certainly a step in the right direction, and away from the "heterophorias," "imbalances," and "graduated tenotomies," which, of late, were rife.

THE INTERNATIONAL MEDICAL ANNUAL AND PRACTITIONER'S INDEX. A Work of Reference for Medical Practitioners. Seventeenth year. New York: E. B. Treat & Co., 1899.

THE present number of the "Annual," like its predecessors, covers the entire field of medicine and surgery, giving in detail all of the important advances in medical science made during the past year, and with full reference to the original sources.

This is one of the best of the yearly summaries, and each page is a convincing proof of the painstaking labor expended in the compilation of the work. We feel convinced that every practitioner needs a work of this description as a means of reference and as a time-saver, when one considers the enormous annual contributions to medical literature. On the whole, the editorial work has been well done, and the busy practitioner will fine the book to be in constant requisition.

DIET AND FOOD. Considered in Relation to Strength and Power of Endurance, Training, and Athletics. By ALEXANDER HAIG, M.A., M.D., Oxon., F.R.C.P., Physician to the Metropolitan Hospital and the Royal Hospital for Children and Women. London: J. & A. Churchill, 1899.

THE author, whose views on diet have been suggested in a monograph on "Uric Acid as a Factor in the Causation of Disease," goes a step further in the little volume under discussion, and lays stress on the elimination from all food of the poisonous xanthins and uric acid. He believes that diet, as at present used, is often the product of much ignorance; the cause of a waste of time and money; that it produces mental and moral obliquities, destroys health and shortens life, and generally quite fails to fulfil its proper purpose. We are not told whether these evils will vanish before a diet composed of milk, cheese, potatoes, pulses, and "protene," such as the author recommends, nor are any facts adduced to prove his contention that "one ounce of albumen from vegetables, milk, or cheese will produce a greater external result than a like amount of albumen from the tissues of dead animals." While the extreme theses of the deleterious nature of meats and of the sufficiency of milk and vegetable diet for those engaged in active physical work are not satisfactorily proven, there is no doubt that overeating of meat is but too common, and the warning note sounded against this practice by Dr. Haig may well be heeded.

THE PRINCIPLES OF BACTERIOLOGY. A Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D., Professor of Hygiene, and Director of the Laboratory of Hygiene, University of Pennsylvania. Fifth edition, enlarged and thoroughly revised. Philadelphia and New York: Lea Brothers & Co., 1899.

IN the present edition of Abbott's well known and popular bacteriology, the subject matter has been brought well up to date, and the book is now one of nearly 600 pages. The work is designed for the use of students, and the author has admirably accomplished his purpose. We know of no other manual on this subject that so adequately fulfils its mission, and in which more painstaking care is given to all the minor details so important to every student, and so frequently omitted from the text-books.

We still, however, must take exception to the limited index, and trust that a future edition will be more complete in this matter. Many new illustrations have been added and the work is a beautiful example of modern bookmaking.

THERAPEUTIC HINTS.

To Remove Odor of Iodoform.—If after washing the hands well with soap and water a teaspoonful of vinegar be rubbed over them the unpleasant odor of the iodoform will be overcome.—*Ricketts.*

VOL. LXXV. NEW YORK, SATURDAY, JULY 8, 1899. NO. 2.

ORIGINAL ARTICLES.

*BICYCLING IN ITS RELATION TO HEART DISEASE.**

BY A. C. GETCHELL, M.D.,
OF WORCESTER, MASS.

IT has been shown, particularly by Allbutt[1] and Da Costa,[2] that continued work at laborious avocations and continuous activity of a milder sort, such as long marches of soldiers, may produce not only functional disorder of the heart, but actual disease of the heart and blood-vessels as well. I propose in this paper to discuss the effect of another kind of continued muscular exertion on the heart, namely, bicycling. In the consideration of the subject I shall divide the riders into two classes, the untrained and the trained. First the untrained. Under this class I include those who are learning to ride and those who ride for pleasure or business only, in contradistinction to the athletic amateur or professional rider.

The accident that these riders are most liable to is dilatation of the heart, and particularly of the right heart, which may be permanent or may last for but a short time. Acute dilatation happens in this wise: Under the stress of prolonged and severe muscular activity the demand for pure blood in the tissues is greatly increased. This is met at first by more rapid breathing and accelerated heart action. But if the demand be too long continued or through special causes, like rapid hill climbing, be too greatly increased, the right heart cannot send the blood rapidly enough through the lungs. Some remains in the right ventricle at the end of each contraction. This amount increases with each cardiac cycle and the cavity is stretched. The rider is now out of breath. If the task he has set out to accomplish is too great, and if he persists the dilated ventricle fails to act, and unconsciousness ensues. Through the cessation of bodily action the heart is relieved of its burden and resumes its function if it have sufficient vitality. On the other hand, if it be diseased death may ensue.

The following cases are examples of this accident, and they illustrate different conditions under which it may happen: Herschell[3] was riding with a friend who was new to the wheel. After pushing up a long hill he noticed that his companion was much exhausted, that his face was pale and his lips blue. He was obliged to dismount and lie upon his back on the grass. Examination showed marked dilatation of the right heart, feeble impulse, and rapid pulse. After an hour he was able to resume his journey, and in the evening the heart was normal.

A patient of mine had a similar experience. He was riding with his sister, and at the summit of a long and gradual ascent reached out to help his companion by pushing her over the crest, when he fell from his wheel unconscious. He soon recovered, and after a time proceeded on his ride. This man was about thirty-five years of age, and had ridden the bicycle for several years. Of late years his health had been very good, though he suffered somewhat from dyspepsia. As a child, however, he was delicate. His father died of heart disease. I have never had an opportunity to make a satisfactory examination of his heart. Once, however, I had occasion to spray into his nose for the purpose of an examination a four-per-cent. solution of cocain. Pronounced and distressing cardiac symptoms immediately ensued, which lasted to a greater or less degree for several hours. At this time I made a superficial examination, but detected no lesion.

A retired wine merchant, while riding over a level road at a moderate pace fell from his wheel and soon died. Autopsy showed rupture of a heart diseased with fatty degeneration, and also a stomach full of an undigested meal.[3]

These are instances of acute dilatation occurring, first in healthy persons who are subjecting themselves to severe exercise, when, as the horsemen would say, they are "soft;" secondly, of those who are inured to the exercise, but who have weak hearts, and, thirdly, of those whose hearts are actually diseased.

It is well recognized that dilatation of the heart occurs in the course of severe illness, and particularly when there is marked febrile movement. Under these conditions there are two factors to be considered in its production: First, the integrity of the heart-muscle, and, second, the resistance to be overcome. In disease the nutrition of the heart may suffer more or less, according to the amount of toxic products which are circulating in the blood. There may be obstacles to the blood current, as, for instance, a consolidated lung.

*Read at the sixteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

The problem is not so clear in the question of dilatation from severe muscular exertion in the well. At first sight it would seem that neither of these factors is present, because physiologically increased activity of the body in the open air would seem to purify the blood, and increased muscular exertion would send it more freely through the tissues. This is true up to a certain limit, and that limit depends upon the relation of two factors, the amount of work to be done, and the ability of the organism to do it. To quote Gibson: [4] "There is one consideration (in the production of dilatation) that must not be overlooked. While the effect of stimulating a muscle in experimental physiology is to accelerate the flow of blood through it, the effect of long-continued muscular action must be to form a large number of waste products, and it will necessarily follow that the blood may have greater difficulty in passing through the tissues after it has been loaded with such substances. The mere muscular exertion, moreover, involved in long-continued efforts is to increase intrathoracic pressure, and this, added to the greater impurity of the blood, will interfere with the functions of the right side of the heart."

In bicycling a proof of the existence of toxic matters in the blood is found in the so-called fatigue fever, which is produced by the absorption of toxins into the blood. In its milder forms it is not uncommon. A personal experience furnishes a good example. One hot day last August with a party I rode over a hilly road to the foot of a small mountain, ascended the mountain, and returned home. The trip occupied the entire day, from 9 A.M. to 5 P.M., with a short rest at the top of the mountain. I was on a tandem bicycle, accompanied on the ride out by a child of ten, and on the return by a lady. I was not particularly tired on my return. During the night, however, I became very restless and could not sleep. My pulse was rapid though regular, and I felt very hot. The experience was so novel, and to me then unaccountable, that I could explain it only on the supposition that I was coming down with some acute illness. After a very uncomfortable night and an unsuccessful attempt to breakfast, I remained in bed during the entire day. I was not a novice at the wheel, having ridden a good deal for ten years. In some instances there is much more cardiac disturbance, and an irritable condition of the heart persists for several days.

The second factor in the production of permanent dilatation of the heart is increased peripheral resistance. This ensues in part as a consequence of the accumulation of toxic products in the blood and in part in the stasis that occurs in the lung owing to the inadequate action of the right heart. Add to these causes the occasional severe strain of spurting and rapid hill climbing and the crouching attitude of the scorcher, and we have causes adequate for much trouble. It thus appears that bicycling may furnish the two conditions for the production of permanent dilatation of the heart, namely, toxins in the blood and increased peripheral resistance.

Dilatation is not the only evil to be feared. Valvular disease may result as well. The auriculoventricular orifices undergo changes in dilatation of the cavities, and thus their dimensions are considerably increased. As a consequence of this the cusps of the valves do not meet as perfectly as in health. In acute illness a murmur, which later dispears, may be heard at these orifices. Under these conditions both the muscular walls and the auriculoventricular ring have not stretched beyond the limits of a possible return to the normal condition. Even if a ventricle weakened by disease has become dilated it is possible by rest and proper treatment to bring about either a restoration to the normal condition or a compensatory hypertrophy. It is doubtful if such a process is possible to an overdistended auriculoventricular ring, and as the cusps remain the same size a permanent disability of the valve must follow.

Let us now consider the effect of the exercise upon the trained rider. The claim is put forth that there can be no danger to men, and indeed women, of this class, since they never are distressed by their exertions. But an examination into the conditions shows that this reasoning does not hold good.

Hypertrophy of the heart as the result of continued and severe muscular effort is regarded as physiological. Thus the hearts of race horses and greyhounds are found to be greatly hypertrophied. Moreover, teachers of gymnastics tell us that the best results in the development of the peripheral muscles are attained by continued exercise against slight resistance rather than vigorous action against great resistance. According to Gibson, a prominent feature in the production of pathological hypertrophy of the heart is its rapid action. Da Costa found hypertrophy to result from the irritable condition which he described in soldiers. Osler says that the condition (*i. e.*, irritable heart) is not infrequent in civil life among young men, and it leads in some cases to hypertrophy of the heart. Herschell is of the opinion that hypertrophy may result from long-continued palpitation.

We have seen that one of the characteristic features of fatigue fever from bicycling is long-con-

tinued acceleration of the pulse. This acceleration also occurs without any fever or uncomfortable sensations. It has been found by a number of experiments with different classes of riders—men, boys, and girls—riding over roads of different grades and against head winds, that after riding at a certain rate, the pulse being counted, if the speed be increased the pulse-rate increases in greater ratio, and that too with the rider feeling no sense of fatigue. Thus the pulse-rate was found to increase from a normal of 72, 74, 80, and 84 to 112, 130, and 140, and in some instances this increased rate was maintained for several hours.

Riders of this class do not suffer from the accumulation of toxic substances in the blood as do their less vigorous companions, and the blood is sent through the tissues with greater freedom. But still there is a certain amount of resistance to be overcome, and when we add to these two factors, namely, long-continued, rapid movement and slight peripheral resistance, a third, good nutrition which is the result of bodily well-being produced by training in the open air, it is readily seen that we have the conditions most favorable to the production of cardiac hypertrophy. This does not mean that all trained bicycle riders suffer from hypertrophied hearts, medically speaking, because their training and life enable them to maintain the nutrition of the heart as well as that of the body at such a state as to fully compensate any alteration of structure. It is said, however, that athletes are liable to rapid deterioration of health when they relinquish their active exercises.[6]

What is the effect of such overexertion on the blood-vessels? As Allbutt has well said, the muscular ventricle may grow both in size of its cavity and in the thickness of its walls, but the walls of the aorta suffer under greater limitations; its power of resistance is great, but its activity is nothing more than the recoil of elastic fibers. Such repeated stretching results not in increased strength, but rather in weakness, as one of the coats may give way and pouching result, or an endaortitis ensue, or indeed incompetence of the aortic valves follow.

Lannois[7] reports a case of rupture of one of the aortic cusps. It occurred in a man, aged thirty-eight years, during a ride from Paris to Madrid, a distance of 1452 kilometers, in nine days. There was not at any time pain or other evidence of the accident, nor was his health impaired, and the lesion was discovered some time later rather by accident.

To summarize: Acute dilatation of the heart is an accident that may be expected from overexertion in an unathletic rider, and if the conditions be repeated permanent dilatation, especially of the right heart, may result with a consequent damage to the auriculoventricular valves. And, secondly, in the athletic hypertrophy may be produced with a possible consequence of disease of the aorta and incompetence of the aortic valve.

In discussing the application of these principles I shall consider three classes of riders: First, young children; second, young adults; third, persons approaching middle life and the unhealthy. Fortunately, in the past the price of a bicycle has precluded its use as a mere toy, and very young riders have been comparatively few. Still one sees them not only in the parks and streets, but in the country as well far from home. I can see no justification whatever for this practice. Boys and girls under thirteen or fourteen should not be allowed to take rides into the country where they may get far from home, and be subject to unwise exertion of a long ride or immoderate hill climbing. I doubt, too, the wisdom of allowing a young child to ride *ad libitum* even in the park or on asphalted streets. The sport is fascinating and not fatiguing, and it is not an uncommon experience to see young children riding hour after hour. Even on a level space, as we have seen, and entirely within the range of non-fatigue, the heart's action may be accelerated, and this increased activity may persist long after the riding is over for the day. Nor does the child escape more serious consequences, as this incident, which occurred in my neighborhood, shows: The child was a girl of twelve, previously fairly healthy. It had been noticed, however, that she got out of breath easily while riding. One afternoon she went into the country, which was rather hilly, with friends for a ride. Nothing unusual was noticed except that she was somewhat out of breath going up hills. She took tea with a friend, and after the meal again rode about the square, this place being slightly hilly also. On going to bed she had some gastric distress, and the family physician was called. He regarded the symptoms as due to indigestion, and prescribed accordingly. The child's room adjoined that of her mother. The latter was wakened in the night by her daughter's distressed breathing. Before help could be called the child died. There was no autopsy, but it is apparent that death was due to acute dilatation of an unhealthy heart pressed upon by a distended stomach.

In the second class of cases, healthy young adults, there is need of precaution against excessive hill climbing and very rapid riding, as the following cases show: C. F., aged twenty years, employed in a sewing-machine factory, consulted me for relief of a frothy expectoration. His family and personal his-

tory was good. He had been a bicycle athlete, and had ridden in many races. His early symptoms were cough, a feeling of substernal oppression, and uncomfortable sensations referred to the cardiac area. He stopped riding and grew better, to resume it after a winter, only to be obliged to discontinue it altogether. His throat and lungs were without evidence of disease. The impulse of the heart, which was feeble, was felt in the sixth interspace just inside the nipple line. The sounds were fairly pure in character, but faint over the tricuspid area, while over the aortic and pulmonic areas the first sound could not be heard at all. In this instance there was dilatation following hypertrophy.

In the following case the opposite conditions prevailed, first dilatation, then hypertrophy: H. B., aged twenty six years. Before the age of twenty he had always been well. Then he began to ride the bicycle. He lived in a very hilly town, was a scorcher, rode a wheel with eighty gear, and never got off for a hill. Presently he found himself unable to ride, and for some time after giving up the wheel was not in good health, having frequent fainting spells. He gradually grew better, and resumed riding but in moderation. His heart presented these features when I examined him five years after his illness: The apex-beat was apparently to the right of and below the ensiform appendix, really the impulse of a hypertrophied right ventricle. There was decided pulsation over the lower right portion of the sternum. Dulness extended one and one-half inches to the right of the median line and three inches to the left at the level of the fourth rib. The first sound over the epigastrium was impure. The pulse was 120 and regular. The rapid pulse was due to the excitement of the examination. He said it was usually 72. But this acceleration showed that the heart was irritable.

In this connection it would be interesting to learn the experience of the surgeons who examined recruits for the army in the late war. I have been able to find but one. In an article in the *Medical Standard*, detailing the results of the physical examination of 9901 officers and men of the Illinois National Guard, Lieutenant-Colonel Charles Adams, speaking of the heart, says: "In the preliminary examination of recruits made by medical officers of different regiments before leaving their home stations many cases of bicycle heart were discovered and the men not allowed to enlist. These were characterized by hypertrophy and dislocation of the apex-beat, with irregular or rapid beat."[18]

Da Costa's tables show that fully two-thirds of his cases happened from the sixteenth to the twenty-fifth year, while the great percentage was from the twentieth to the twenty-fifth. These figures are fairly reliable for our present purposes, because our army was recruited from men of the same class as our bicycle army. Men then, and women also, who take to the wheel between the ages of twenty-five and thirty-five, if healthy, are little liable to trouble because their physical powers are matured, and also because as a class they are not apt to indulge in the excesses of the more youthful.

From the age of forty, however, conditions are likely to be different. Those who begin to ride at this time in their life are the man of leisure or the bookkeeper or clerk, people who have spent the greater part of their life indoors, have very probably been high livers, and as a consequence suffer from faulty nutrition. To such the bicycle may be a blessing or a positive danger. Proper regard for hills, excessive exercise against high winds, rough roads, and the gear of the wheel will make the exercise beneficial, while one indiscreet overexertion may cause irreparable injury.

And, lastly, those who seek medical advice for ill health, such as dyspepsia. In all such cases before advising the use of the bicycle the heart should be carefully examined, for it must be remembered that the symptoms for which the patient seeks relief may derive their origin from some disorder of the heart or blood-vessels. Indeed, instances are on record of persons by bicycling, at first getting much relief from their dyspeptic or gouty symptoms, only later to fall victims to fatal disease of the heart. Under these conditions an examination of the heart should be exhaustive by the use of every means at our disposal—palpation, percussion, mensuration, and auscultation. The slightest deviation from the normal condition, whether it be in the character of the sounds, the relative intensity of the first and second sound in any area, their relative intensity in different areas, the rhythm of the heart, the character of the impulse, the condition of the arteries should be carefully noted, for it may be the heart that presents no gross lesion is the dangerous one, and the one that soonest breaks down under a severe strain.

Even if cardiac or circulatory lesions are found it does not follow that the bicycle should be forbidden, but it must be prescribed. Definite regulations must be laid down as to the character of the road, the length of periods of exercise, the kind of wheel, and the size of the gear. From personal experience I feel sure that proper bicycle riding will materially strengthen a weak heart, as it undoubtedly improves the general nutrition of the body. My contention is not that bicycling is a harmful mode of exercise. Indeed, I hold to the opposite view very

strongly. Bicycling is productive of great good, both in the way of health and of pleasure. But at the same time we must recognize the fact that it presents peculiar temptations to excessive exertion that is dangerous.

The athlete will probably go his way without asking or taking our advice. But we should be in a position to influence the youth in our midst, and especially those who seek medical advice If the bicycle is prescribed as a therapeutic agent for any trouble including disease of the heart it must be carefully prescribed, and not merely recommended, leaving the patient to his own inclinations and possible indiscretions.

THE PROGNOSIS OF PNEUMONIA IN ITS RELATION TO ITS ETIOLOGY.[1]

BY HERBERT MAXON KING, M.D.,
OF GRAND RAPIDS, MICH.

THE clinical picture presenting in acute lobar pneumonia is so constant in its essential features, while its pathology is so comparatively undeviating, that a single well-defined case may be taken as a type from which variations are few and unimportant. Its pathologic aspect is clear, well defined, and characteristic, and in that sense pneumonia is always one and the same disease, whether primary or secondary, mild or severe, and whether terminating by crisis or lysis, recovery or death. For this reason I think we have come to base the prognosis too much upon the physical condition and environment of the patient and too little upon the etiology of the disease, which, it is scarcely necessary to demonstrate, is by no means always one and the same.

Pneumonia is a term applied to a pathologic condition, the chief and characteristic lesion of which is found in the lung. It was employed to denote an acute lobar consolidation before the bacterial origin of such a condition was discovered, and it is, unfortunately, still employed indiscriminately to describe a pathologic process which, however uniform its morbid anatomy, is not at all so in its causative factors. It is time, therefore, it seems to me, in the light of present knowledge, that we cease to apply this term to all acute lobar consolidations; or, better still, that we, continuing to use the term purely with reference to its characteristic anatomic lesion, shall in every case modify it by a proper adjective to denote the true nature of the disease process as relates to its etiology. In other words, that we shall name each pneumonia for its ultimate causative factor so far as it is possible. As, for instance. "pneumococcic" pneumonia, "streptococcic" pneumonia, "influenza" pneumonia, etc. I maintain that it is just as unwarrantable to neglect the exact determination of this feature in pneumonia as it would be in a case of suspected phthisis. Indeed, the steps necessary to be taken for this end are equally simple and very similar in both phthisis and pneumonia.

When this procedure shall have become a practice the prognosis in lobar pneumonias will cease, to a very large extent, to be based upon "personal equation," and we shall be eminently better qualified to estimate upon the probable course and outcome of the disease. Moreover, the knowledge thus added at the outstart will, no doubt, simplify and make more exact the treatment of the individual case. Vital statistics, when compiled with this feature in view, will have much more meaning, and for their practical application they will possess a much greater value to the sanitarian.

It is my object here, however, simply to point out the importance of ascertaining the nature of a pneumonia with relation to its etiology for the purpose of more accurately prognosticating the issue in any given case. To illustrate this point, permit me to cite briefly from my records of several typical cases among those which have come under my observation since having had this feature in mind.

CASE I.—Male, between fifty and sixty years of age, farmer by occupation. The history of the attack was typical. After a hard day's work, during which the patient felt as well as ever, he was suddenly taken with a severe rigor, followed by fever and attended by sharp pain in the right chest; a dry cough, followed by "brick-dust" expectoration in due time, great prostration, and at times a low delirium. Toward the end of the second week his temperature became remittent, with afternoon exacerbations and occasional sweating.

I saw the case in consultation early in the fourth week in the afternoon. The patient's temperature was 103° F.; pulse, 110. There was complete dulness over the lower right lobe, less marked over the middle lobe, and quite perceptible over the left lower lobe. Vesicular murmur was lost in the middle, right and lower portion of the lower left lobes,

[1] Read before the Michigan State Medical Society at Kalamazoo, Mich., May 4, 1899.

and no respiratory sounds whatever were to be heard over the lower right lobe. Expectoration was profuse and of a dirty brick-dust color. The urine was non-albuminous, responding negatively to Ehrlich's diazo-test.

Microscopic examination of the sputum demonstrated the presence in enormous number of the pneumococcus of Fraenkl, with practically no other micro-organisms. (This was rather unexpected in view of the remittent character of the temperature and the sweating, which suggested sepsis.) The diagnosis, based upon the findings, was acute pneumococcic lobar pneumonia, and the prognosis was very favorable for complete recovery, provided a secondary streptococcic or other pyogenic infection did not occur.

If seen early in the course of the disease such a prognosis could not safely have been made, for it is in these pneumonias that death on the eighth to twelfth day from acute toxemia occurs, but, having survived the first shock, the outlook for recovery was favorable. I have since learned that convalescence was slow but uneventful and complete.

Case II.—This case was under my own observation from the first, so that I had an excellent opportunity for complete investigation: Female, twenty-eight years old, had been under observation and treatment for pulmonary tuberculosis involving the left apex for two months prior to the onset of the pneumonia. She was feeling ordinarily well and was able to attend to her usual occupations. After two days of slight indisposition and moderate elevation of temperature a sharp rigor and rise in temperature to 105° F. occurred. Pain in the left chest, dyspnea, and prostration marked the onset of an acute lobar pneumonia, involving the whole of the left lung. Consolidation was the most complete I have ever seen. There was absolutely no respiratory sound except a bronchial tubular breathing, which came to the ear with a metallic, almost musical, sound. Cough and expectoration were entirely suspended. Exploratory aspiration failed to show fluid in the pleura or lung. Cyanosis of the lips and nails was marked. Passing over irrelevant details of the case the crisis occurred on the thirteenth day, with distinct improvement in subjective symptoms following immediately, and a return to some extent of the cough, which had been absent since the initial chill. Expectoration was, however, very scant. A glairy mucus by microscopical examination was shown to contain tubercle bacilli in "clumps" resembling pure cultures in arrangement, but there were no other micro-organisms. Within a few days the expectoration became mucopurulent and the tubercle bacilli gradually lost this peculiar arrangement, but were the only organisms found in the expectorated matter.

It is of interest to note that prior to the pneumonia cough was a persistent symptom. Expectoration was much more profuse and more purulent in character, while the bacilli were more scattered throughout the specimen. With the supervention of the typical pneumonia I was prepared to find a secondary pneumococcic infection, but as soon as expectoration was procurable the diagnosis of acute tubercular lobar pneumonia was made and a prognosis favorable, so for at least as recovery from the pneumonia was concerned, was allowed. It is in such a pneumonia as this, however, whether preceded by evidence of pulmonary tuberculosis or not, that hydrothorax is apt to occur as a complication, and, indeed, a serous effusion into the pleural cavity occurring in the course of a pneumonia may be taken as proof positive of the tubercular nature of the pneumonia just as purulent effusion in the course of pneumonia may be taken as evidence that the pneumonia is due, if not entirely, at least in part, to infection by pyogenic organisms.

In the case in point resolution proceeded slowly but uninterruptedly and the lung cleared up, leaving the patient no worse off than she was before the pneumonia. Subsequently, however, a serous effusion into the pleural cavity occurred and about three pints of fluid was aspirated.

Case III.—Female, about thirty-eight years old. A protracted, difficult placenta-previa labor was followed, at some interval, during which septic fever occurred (the history obtained was indefinite and vague), by phlebitis, and ten days after labor by the initial symptoms of acute lobar pneumonia, involving the two lower lobes of the right lung. This pneumonia ran an irregular course for three weeks, when abscess and necrotic changes became evident and I saw the patient for the first time. The breath was horribly foul, and expectorated matter contained shreds of broken-down lung tissue, pus, and the usual abscess detritus. The chief micro organism found besides the saprophytes, always present in such conditions, was the streptococcus pyogenes in chains of from ten to thirty elements. There were no pneumococci, influenza, or tubercle bacilli. The case was, therefore, one of acute streptococcic lobar pneumonia, probably originating in a septic thrombus from the involved veins in the extremities. The prognosis, when I saw the patient, was favorable for recovery, without serious complications or sequelæ.

Had a bacteriologic examination been made before the formation of abscess I have no doubt streptococci would have been the prevailing organism found. The prognosis then could have been made with fair degree of certainty as follows: Favorable for eventual recovery, with the probabilities, however, in favor of abscess or empyema as complications, and more or less impairment of the lung as a result.

Of course, necrotic changes occurring in the course of streptococcic pneumonia cannot ordinarily be foreseen. Gangrene, rupture of a pus-sac into

the pericardium or peritoneum, etc., must be regarded as *accidents* which cannot fairly enter into consideration in the prognosis of such cases. In the case in point, however, originating as it did presumably from a thrombus, necrosis was to be expected. This patient lived up to my expectations, and is at present quite well, although convalescence, as might have been expected, was tedious.

Case IV.—The last case which I shall cite in illustration is also one in which I have enjoyed excellent opportunity for study: Female, between fifty and sixty years of age, appeared with symptoms of a bad "cold," congestive rhinitis, dry cough, pain in the head, back, and legs, some rise of temperature and pulse rate, with slight rigors. For two or three days these symptoms continued, the fever increasing with great prostration, and on the fourth day a more severe chill with temperature of 103.5° F. was followed by the appearance of physical signs of lobar pneumonia involving the lower lobes of both lungs. The cough, which had been dry and persistent heretofore, now became productive of a mucopurulent expectoration which contained Pfeiffer's bacillus of influenza in great abundance; there were no other micro-organisms in sufficient number to be characteristic, and no pneumococci at all.

The diagnosis thus established at the very start was acute influenzal lobar pneumonia, and the prognosis was of necessity guarded, but on the whole favorable. The case pursued an irregular course, uncomplicated by other infections. Consolidation gradually disappeared, there was no crisis, and a tedious and protracted convalescence left the patient in a deplorable nervous condition.

There was no pleuritis during the course of this pneumonia, and of course no tendency to effusion; indeed, I have never seen the pleura affected in uncomplicated influenza, and do not believe such complications ever arise without other infection than that by Pfeiffer's bacillus. This is a broad statement, but one which I think will be borne out by observation. Many cases of pleuropneumonia, so-called pleuritis, dry and with effusion, are reported as "grip" complications, but so far as my experience or information goes these complications arise from multiple infections, made more easy, no doubt, by the depletion of the system by true influenza toxemia, but never directly due to Pfeiffer's bacillus, which we must admit as the sole origin of this peculiar toxemia.

In these illustrations I am aware that some objection is reasonable on the ground that such single infections are not the rule and that the great majority of pneumonias not dependent upon the pneumococcus are multiple infections. Moreover, many pneumococcus pneumonias, especially those running an irregular course, are no doubt cases in which from the start or sometime subsequent to the initial chill there is infection by more than one organism, but I have purposely chosen these cases of single infection to better illustrate the point, and while any pneumonia may present in a sputum examination several varieties of pathogenic organisms, there will always be found *a predominating, and so to speak, primary germ*, upon the natural parasitic history and pathogenic properties of which will to a very large extent depend the prognosis of the disease. The cases cited, then, are typical, and will, I think, be found safe guides so far as they go. There are, no doubt, pneumonias which do not fall into any of the classes mentioned. Further study with this idea in view by many observers will be necessary not only to make prognosis in such cases a more definite matter but to place a clinical value upon my own experience and corroborate or falsify my conclusions.

First, then, in conclusion, a pneumococcus pneumonia occurring in a previously healthy individual under sixty-five years of age tends to recovery by crisis, runs a distinct and definite course, is not complicated by pleural effusions, and, in patients who recover, does not permanently affect the integrity of the lung or cause abscess or gangrene. On the other hand, it furnishes by far the greatest pneumonia mortality; and death in the fatal cases is due to acute toxemia.

Second, tubercular pneumonia, occurring either as the initial stage of pulmonary tuberculosis, or in the course of the latter disease, runs an acute and oftentimes alarming course, is more irregular in its development, may terminate by crisis as distinct as that in pneumococcus pneumonia or by gradual subsidence, *is not attended by suppuration*, either in the lung or pleura, may, however, produce pleuritis, dry or with profuse serous effusion, is seldom, if ever, immediately fatal, and it is doubtful if its remote results upon the general tuberculous process are harmful.

Third, streptococcic pneumonia (including all pneumonias dependent upon infection by pyogenic organisms) forms a very large proportion of all pneumonias, runs a very irregular, prolonged and atypical course; is always the class in which empyema, abscess, or gangrene of the lung is to be feared; is the pneumonia in which septic complications in other organs are to be looked for, and in case of recovery of the patient, often more or less seriously impairs permanently the integrity of the lung or pleura.

Fourth, influenza pneumonia, if uncomplicated, runs a shorter course, in which less-marked disturbance with the body temperature is associated with much greater disturbance of the vasomotor nervous system and with profound prostration, does not tend to terminate by crisis, does not involve the

pleura, nor of itself permanently affect the integrity of the lung, and is seldom of itself fatal. On the other hand, this class of pneumonias more than any other predispose the lung to infection by other pathogenic organisms, among the more frequent of which (probably because of their omnipresence) are the streptococcus and tubercle bacillus, consequently this pneumonia is, more than any other, subject to complications and sequelæ arising from multiple infections.

When the bacteriologic examination relegates a pneumonia to its special class then a prognosis may be safely based upon such general principles as I have endeavored here to outline, guarded, of course, by the condition that it shall remain within its special class and subject to such modification as subsequent examination (which, it is needless to say, should be frequent) shall demand

It must be remembered that while almost all pneumonia sputum is likely to present many varieties of micro-organisms there will be *one* variety which will prevail in such predominance as to enable the physician to classify the case and with the exercise of sound judgment prognosticate its issue with a fair degree of certainty.

Finally I have purposely avoided citations from the prodigious amount of literature on the subject of prognosis in pneumonia; first, because in such a paper as this, to be read before a society, the chief object to serve is that of exciting a full discussion, an object which is too often defeated by tedious and unnecessary annotations and references, consuming time which could otherwise be given to discussion; and second, because in the literature to which I have access I have failed to find anything which takes up this subject from the point of view which I have endeavored to assume.

MEASURING THE INTENSITY OF THE HEART TONES.

By ALBERT ABRAMS, M.D.,
OF SAN FRANCISCO.

It has no doubt been a source of regret to many physicians who are habitually engaged in the examination of the chest that we are in possession of no accurate means of registering the heart tones to facilitate accuracy in determining the progress of our patients with heart lesions, or the action of cardiac tonics. There are different factors which normally determine the loudness of the heart tones. One factor is the varying conductivity of the different structures in the chest wall and between the thoracic wall and the heart. The chief factor, however, is the strength of the heart's action. Auscultation of the heart tones in the conventional manner not infrequently affords us no indication of cardiac strength if reliance is to be placed on the intensity of the tones in their selective propagation to different parts of the chest.

I have often been struck by the loudness of the heart tones in emaciated individuals in whom the action of the heart was found to be feeble, as determined by the sphygmomanometer and sphygmograph. In convalescents from typhoid fever the foregoing fact has been especially emphasized in not a few instances. In anemics we often hear very loud tones, even though the blood pressure is low, and again in dilatation of the stomach when that organ approximates the cardiac area, the tones by mere resonance are loud, even though the strength of the heart is reduced. In many emaciated persons it often happens that the heart tones are conveyed to the interscapular region, to the epigastrium, and even the head without any corresponding increase in the force of the heart. In such instances the thorax is practically a resonator. If then, in certain instances, auscultation is no trustworthy index to the force of the heart, have we not in the sphygmomanometer and sphygmograph clinical instruments of sufficient reliability to gage the blood pressure? Unfortunately, in the application of these instruments we must contend with the objectional personal equation and content ourselves with the determination of the blood pressure in the systemic circulation only. When the phonograph was first introduced I thought I saw in that instrument the consummation of my hopes, but after considerable experimentation it proved useless. In my "Manual of Diagnosis"[1] the results are expressed as follows: "In my investigations, which were varied in every manner possible, the recording of heart sounds was practically impossible. The fault rests with the phonograph. There is no question about the sensitiveness of the diaphragm for recording even the feeblest sounds, but the difficulty lies in reproduction. Even loud sounds emanating from the chest are with difficulty detected by an ear accustomed to the phonograph. When the reproducing needle is adjusted to the revolving wax cylinder a hissing sound is heard, the result of friction between the needle and the wax. It is this sound which interferes with proper reproduction. If this objection were obviated the phonograph would prove an ideal instrument in physical diagnosis."

The following method for measuring the heart tones is suggested for its simplicity. It is only relatively accurate. It is based on the simple physical principle that the intensity of sound varies inversely as the square of the distance from the sounding body,

[1] "Manual of Clinical Diagnosis," third edition, 1894.

hence the distance to which a heart sound may be heard depends upon its intensity, ignoring of course those adventitious causes of propitious conductivity. Between the area auscultated and the stethoscope a medium is interposed. Experiment has taught me that one of the best media is partially vulcanized rubber in the form of a rod, and just sufficiently soft as not to interfere with convenient manipulation. Such rods may be purchased in any store where rubber goods are sold. The circumference of the rods must equal the caliber of the pectoral end of the stethoscope in which they are to be inserted. The degree of insertion must be regulated by a notch cut into the rubber. The object of this regulation is to insure uniformity of results in the examination of individual patients. The rods may be of different sizes, varying in length from 6 to 26 centimeters, or even of greater length. Before auscultating the heart tones by this method, we must first mark on the chest the different points in the precordial region where the heart tones are heard with the maximum degree of intensity. Over each ostium we auscultate with the rod inserted into the end of the stethoscope, beginning with a rod of medium length and gradually increasing the length of the rod until one is attained through which the heart tones are no longer conducted. The tubes are numbered, and a record may be made in our case book after the following formula:

Mitral, I. tone	—6
" II. tone	—5
Aortic I. tone	—4
" II. tone	—5
Tricuspid I. tone	—6
" II. tone	—4
Pulmonary I. tone . . .	—4
" II. tone . . .	—5

According to the foregoing formula we conclude the following: That with a rod (No. 6) which is 26 centimeters in length we may still be able to hear the following tones: Mitral systolic and tricuspid systolic tones. A similar interpretation may be deduced from the other numbers. These figures possess no value for general application as the degree of transmission is dependent on the character of the stethoscope as well as the length of the rod employed. Each observer must cut his own rods of different lengths. With some kinds of stethoscopes the first mitral and tricuspid tones are still heard with rods fully 30 centimeters in length, whereas with other kinds a rod of half the length will no longer transmit the same tones. In some instances another method may be adopted. It is less reliable than the former method, especially in thin persons, owing to the increased conductivity of the thoracic tissues. As before, one marks on the chest wall the different situations where the heart tones, corresponding to each ostium, are heard loudest, and then proceeds in different directions until the sounds are no longer audible. The distance to which the sounds are propagated is marked and measured. The directions in which the sounds are auscultated have been determined empirically as follows:

Mitral Tones.—Auscultate along a line on a level with the apex-beat to the left axillary region.

Tricuspid Tones.—Auscultate along a line extending from the point of auscultation to the right axillary region.

Aortic Tones.—Along a line on a level with the point of auscultation to the right axillary region.

Pulmonic Tones.—From the point of auscultation to the left axillary region. The tricuspid and mitral tones are best conducted downward by the liver, but as a differentiation of the mitral and tricuspid tones over the hepatic region is impossible this direction cannot be employed. I will mention, parenthetically, that the liver is an excellent conductor of the heart tones, and when they are no longer audible by auscultation we can safely conclude that the lower border of the liver has been reached.

The following conclusions may be formulated:

1. The loudness of the heart tones may be measured by testing the distance to which they are transmitted from their clinical point of auscultation.

2. This may be determined by two methods. The first method consists of measuring the distance to which the heart tones are propagated along definite routes on the chest. The second method consists of introducing between the stethoscope and the chest wall a soft rubber rod of varying length, the tones gradually becoming less distinct as successive rods of increasing length are employed.

3. Of the two methods the latter is by far the more accurate, although this by no means represents an ideal attainment.

4. The employment of either method does away with memory in observing the progress of the strength of the heart in individual cases, and enables us to distinguish more easily any accentuation of the tones.

5. The order in which the tones can no longer be heard is as follows, beginning with the weakest tones: First aortic, first pulmonary, second tricuspid, second mitral, second aortic, second pulmonary, first tricuspid, and first mitral tone.

6. Until a universal stethoscope is employed we cannot hope to make the method of measuring the heart tones of general application, but must content ourselves with the application of the method to individual cases.

7. The first point beyond the hepatic region where the cardiac tones are no longer audible marks the lower border of the liver.

CLINICAL MEMORANDUM.

TETANUS TREATED BY ANTITETANUS SERUM; REPORT OF A CASE.[1]

By T. E. TAYLOR, M.D.,
OF DENVER, COL.;
PROFESSOR OF OBSTETRICS IN THE UNIVERSITY OF COLORADO; ATTENDING OBSTETRICIAN TO THE COLORADO COTTAGE HOME, AND TO THE ARAPAHOE COUNTY HOSPITAL.

THE frightful mortality attending tetanus when left to run its natural course, and the almost complete failure of the ordinary therapeutic measures to favorably influence the course of the disease, leads us to look with favor upon any new remedy which promises benefit. The demonstrated infectious nature of tetanus, and the accepted therapeutic efficacy of the antitoxic treatment of diphtheria, and in minor degree, the streptococcus infections, together with the successful immunization of animals against tetanus cultures by injections of antitetanus serum, give a rational basis for the trial of this product in cases of developed tetanus. The considerable number of recorded cases exhibits a diminished mortality; and as in many of the fatal cases the serum was used only after the disease had already continued several days we may hope for a greater improvement when it is used early. Such a favorable case I am able to report:

Mrs. J., married, mother of two children, called on Dr. A. E. Grant to attend her on January 27, 1899. She gave a history of a long series of miscarriages and resulting uterine disorders, and stated that for several days she had been flowing excessively, and something had passed from her which was destroyed without examination. She had missed one period, and she supposed her menstruation was so profuse for this reason. She strenuously denied having in any way induced an abortion. On January 24th, three days before, she had experienced chilly sensations, and thought she had caught cold.

As the hemorrhage was severe, and Dr. Grant had no gauze or cotton with him he tamponed the vagina with a clean cloth furnished by the patient, which was soaked in a solution of mercuric bichlorid. Next morning she complained of stiffness of the neck and jaws, not being able to separate her jaws more than half an inch. Alarmed by these symptoms, Dr. Grant proposed a consultation. We saw her soon after noon, when in addition to the difficulty in opening her jaws and stiffness of her neck, she complained of soreness in the thoracic muscles. The facial muscles were not noticeably affected, though there was heightened reflex irritability. Her temperature was 99.5° F., and pulse 95.

We agreed that a thorough curettage of the uterus and irrigation of its cavity was indicated, and this was done, the uterus being irrigated with a solution of bichlorid 1 to 4000, and the uterus and vagina packed with iodoform gauze. She was then returned to bed and ordered full doses of bromid and chloral (though nausea prevented much being administered), and 4 c.c. of Parke, Davis & Co.'s antitetanus serum was injected under the skin of the abdomen. We saw the patient again together at noon on January 29th, and found the stiffness of the neck and jaws nearly gone. She was given an additional injection of 6 c.c. of serum. The nausea still prevented the administration of much medicine by the mouth. The packing of the uterus and vagina was removed and an antiseptic vaginal douche given. On the following day the stiffness of the muscles had entirely disappeared and the patient made an uninterrupted recovery.

This termination of such a grave disease is as unusual as it is gratifying. Indeed, it is so very unusual that it compels a close scrutiny of the diagnosis, for of all the forms of tetanus that following an abortion is perhaps the most hopeless. Gowers says that recovery is practically unknown. There are only two other conditions which could have been mistaken for tetanus in this case—hysteria and rheumatism. The latter frequently causes a stiffness and soreness of the muscles of the neck not unlike commencing tetanus, but rarely if ever affects the jaw. The patient was not subject to rheumatism, and had not caught cold, while her abortion, possibly self-induced by septic instruments, had certainly opened a channel for infection. Hysteria may more or less closely simulate tetanus. In regard to the differential diagnosis Gowers says: "In hysteria, tetanoid spasm is rare except as part of a convulsive attack, but trismus causing persistent closure of the jaws occurs in hysteria. It may succeed a convulsion and last till another, or may come on without obvious cause, continue a few hours or days and then suddenly vanish. It is prone to recur, and this character, the suddenness of onset, its complete degree, the absence of rigidity in the neck, and the presence of other symptoms of hysteria rarely leave any doubt as to its nature." There were no other symptoms of hysteria, nor was there any history of previous hysterical attacks, so that this fact, with the marked rigidity of the neck, enables us to exclude this condition.

White and Peterson say of hysterical trismus: "It usually appears suddenly after a hysterical convulsion and suddenly disappears and recurs, and lacks the nuchal rigidity and mental clearness of tetanus." The prompt response of the disease to the injection of the serum, which was used as soon as the diagnosis was made, favors the view that one reason for the slight benefit of serum treatment of tetanus hitherto has been its too late use. White and Peterson enjoin the early use of the serum, in addition to other therapeutic measures, and express the hope that it may be improved so as to be more efficacious.

[1] Read before the Colorado State Medical Society, June 20, 1899.

MEDICAL PROGRESS.

An Obscure Complication of Varicocele.—SMYTH (*Montreal Med. Jour.*, June, 1899) mentions a peculiar complication in a case of varicocele. It was a nodular mass which appeared in the upper part of the scrotum, very

tender and giving the patient intense pain. The testicle was not affected nor was there anything to be felt in the inguinal canal, though the dragging pain extended upward into it. Manipulation under chloroform produced no evident effect, and aspiration with a needle drew only fifteen minims of dark blood. The patient was taken to the hospital in an ambulance. During the journey he felt a sudden relief, and examination a short afterward showed that the tenseness had entirely disappeared. There was in the upper part of the scrotum a soft, tender nodule, apparently the result of the numerous hypodermic pricks, and a tender nodule was felt to the inner side of the internal ring. Operation was performed but nothing was found. The writer considers the differential diagnosis between hernia and a strangulation of one vein by the loop of another, and decides in favor of the latter complication. The patient recovered.

Cleaning the Hands with Horsehair.—FORBES (*Phil. Med. Jour.*, May 20, 1899) takes a flat bunch of curled horsehair instead of a brush and uses it in cleaning his hands, and preparing the operative field. The hairs are stiff enough to scrape away particles of dirt, and will not scratch the most delicate skin, as will the bristles of a brush. This little mop of hair can be sterilized and used for months without losing its character.

Neglect of the Teeth before and after Dentition.—HEAD (*Ther. Gaz.*, May 15, 1899) takes to task those who prescribe acid medicines without cautioning patients to protect their teeth from their influence. He says many a dentist has carefully brought a child up to the age of fifteen years, and then has seen his efforts spoiled by the medicine given in some acute illness. Another precaution wofully neglected is the washing of the mouth every four hours, during a severe illness. Some mild antiseptic solution should be held against the teeth for not less than two minutes each time. Milk of magnesia should be used at bedtime to protect the teeth from acid mucus during the night.

Head is a strong advocate of the lancing of painful teeth in infants. The pressure of one tooth upon a healthy nerve, while its edge is cutting through the gum, may not upset a child. But if the child is irritable, or if several teeth are coming at once, the physician should lance the gums. There need be no dread of making the gums hard by scar tissue, as no tissue in the body is more yielding than that of a scar.

Results of Operation for Stricture of the Urethra.—ISRAEL (*Deut. Zeitschr. f. Chir.*, vol. 51, p. 239), after an examination of the records of all the patients with stricture operated upon during the past eight years in the Moabit Hospital in Berlin, combined as far as possible with an examination of the patients in their present condition, advocates internal urethrotomy rather than external urethrotomy in all cases in which the stricture is in the bulbous portion. He found this to be the commonest seat of stricture, those patients who had strictures in the pendulous portion usually having one in the bulbous portion as well. Four patients died after operation, one of the deaths being due to miliary tuberculosis, and the others to shock, uremia, and sepsis. These all occurred in patients upon whom external urethrotomy had been performed.

Celluloid Thread for Sutures and Ligatures.—PAGENSTECHER (*Deut. Med. Woch.*, April 6, 1899) takes a good thread, boils it for half an hour in a one-per-cent. solution of soda, washes it in boiling water, and then dries it between sterile compresses. He then soaks it in a solution of celluloid, and passes it again through the same solution. Afterward it is sterilized by steam under pressure, and preserved for use either dry or in an alcoholic solution of bichlorid of mercury. Such threads have a smooth surface, they never tangle, they cannot absorb secretions, and are easily tied. For three years Pagenstecher has used these celluloid threads, to the exclusion of silk, and the use of catgut for ligatures has been greatly reduced. The results have been of the best, and the saving in expense considerable.

Trophic Affections of the Bladder Following Pelvic Operations.—After such operations, especially vaginal hysterectomy, symptoms of cystitis sometimes appear which are attributed to the presence of ligatures in the wall of the bladder. MIRABEAU after cystoscopic examination of a number of such cases states the condition to be one of atrophy of the mucous membrane with areas of edema which he attributes to trophic disturbances resulting from section of nutrient vessels. He found no ligatures. He considers the usual treatment, especially intravesical treatment, to be injurious, and advises stimulation of the local circulation by means of abdominal and vaginal massage, applications of iodin, glycerin, and sitz baths.

THERAPEUTIC NOTES.

A Common Cause of Crying in the New-Born and Its Relief by Water.—SOUTHWORTH (*Canada Lancet*, May, 1899) suggests that the uric-acid infarctions in the kidneys of the new-born may be a source of irritation and a cause for crying if the scanty supply of urine washes them out with difficulty. Thus a baby which had cried almost all of the second day of its life and had passed, during this time, no water, emptied its bladder of a half ounce of turbid brown urine when the cool hand was placed upon it. Boiled water, which should be given to the infant regularly pending the establishment of lactation, will dilute the urine and alleviate such discomfort.

Posture in Occipitoposterior Positions.—GREEN (*Bost. Med. and Surg. Jour.*, May 25, 1899) says that the advantage to be gained in the treatment of occipitoposterior positions by a proper application of the force of gravity is not as well known as it should be. He mentions an instance in which he was able to obtain a change from a posterior to an anterior position after the rupture of the membranes, but before pains had come on, simply by keeping the mother kneeling at the bedside a good part of the day. The following day she was delivered, after

four hour's labor, of a ten-pound child. Even after the head is in the pelvis the assumption of a lateroprone position on the side toward which the occiput is directed will generally effect rotation in cases in which it could only be brought about by manual interference if the patient remained continuously on her back. During the last week of pregnancy Green often advises a woman to lie at night in the lateroprone position, on the side toward which the occiput is directed, being able thereby to convert a posterior into an anterior position. During the first stage of labor the kneeling posture can be assumed from time to time with profit and comfort to the patient. When rotation has been obtained delivery can be accomplished in any prone position that is preferred.

The Control by Arsenic of the Ill Effects of Thyroid Extract.—MABILLE (*Rev. de Therap.*, May 1, 1899) hopes that he has found in arsenic a means of preventing the ill effects of thyroid extract, which are produced in some patients by this drug. The increased use of the thyroid gland, not only for myxedema, but for obesity, goiter, certain skin diseases, and in general for malnutrition, makes it important that there should be some means of controlling the vertigo, palpitation, dyspnea, anxiety, etc., from which patients who are particularly sensitive suffer. The writer observed that these symptoms disappeared in one of his patients when she was taking Fowler's solution and reappeared when she stopped the arsenic. From 2 to 12 drops of Fowler's solution at a dose were found to be sufficient to prevent any unpleasant symptoms even when taking 12 grains a day. Two other patients took arsenic with thyroid extract with happy results, and the arsenic did not weaken, apparently, the force of the thyroid extract.

Bromid of Ethyl Anesthesia —LARISCH (*Centralbl. f. Chir.*, April 15, 1899) gives in the form of an inaugural dissertation the experience of Partsch with bromid of ethyl narcosis. After using this anesthetic upon more than 120 patients this surgeon is enthusiastic in its favor, and regards it as an ideal anesthetic. The accidents which followed its use some years ago and which gave it such a bad name were due, he claims, to the administration of too much or too-concentrated vapor, or to the use of impure preparations. He employs only the purest drug (Merck's manufacture), dropping it on an ordinary chloroform mask. A stage of excitement was observed in only eight per cent. of adults and in no children. All patients wakened from unconsciousness very quickly and vomiting occurred in less than two per cent. of the cases. As the heart-beat and respiration are scarcely affected by it, the anesthetic is particularly useful in cardiac cases, and as it is quickly dissipated from the system, but not at all by the kidneys, it is recommended for use upon patients suffering from grave constitutional maladies, such as diabetes, sepsis, etc. The reflexes are never entirely abolished during its administration so that it requires a little practice to know how deeply a patient is under it, but the muscular system is sufficiently relaxed to permit of the reduction of fractures, etc. For use in minor surgery it has no equal.

The Coated Tongue.—WEAVER (*New York Med. Jour.*, May 13, 1899) says that the coating of the furred tongue is full of fungi, and that the bacteria, innocent or infectious, as the case may be, are washed into the stomach with each meal. In disease there are abnormal elements in the secretions and excretions. When abnormal saliva is thrown into the mouth and subjected to the action of the numerous micro-organisms of fermentation, more or less of the solid matters are thrown down and constitute a salivary precipitate, which lodges on the teeth and on the dorsum of the tongue, also on the gums and lips, which, in cases of typhoid fever, is known as sordes. This salivary precipitate can be recognized on the teeth, as it roughens their surface. It is easily removed by the use of the tooth brush. It covers the teeth as a whitish deposit which microscopically shows the different forms of micrococci and bacilli. Upon the tongue it is allowed to remain until it becomes very offensive, unless it is systematically removed by scraping.

When a physician is consulted regarding a foul breath or coated tongue he ought to advise the patient to procure a tongue-scraper and diligently clean the tongue every morning as a part of the morning toilet, using after it a disinfectant mouth wash on the tongue and as a dentifrice. This method will remove the foulest odors from the breath. The same deposit appears on the tongue every morning and must be removed as often.

Every surgeon who has a coated tongue and wishes to be aseptic should look to this possible source of infection, for in coughing, sneezing, or even speaking, it is known that the breath takes with it particles of moisture from the mouth and throat. And every patient who is to have an operation about the mouth or throat should have his tongue cleaned and disinfected. Every fever patient should have his tongue systematically cleaned to remove just that much self-infection. And every person who wishes to be agreeable in the society of others should remove the foul coating on the tongue and with it the offensive odor of the breath.

Prophylaxis of Ophthalmia Neonatorum. — CASTILLO (*Rev. de Therap.*, April 15, 1899) says that many troublesome affections of the eye, which sometimes result in blindness, might be avoided if accoucheurs were more careful in the use of prophylactic measures. The genitals of every pregnant woman ought to be minutely examined. If there is a leucorrhea it should be examined bacteriologically, since the presence of gonococci introduced perhaps by the father, who thinks himself completely cured of an old gonorrhea, makes antiseptic irrigations preceding the confinement especially necessary, though they should be used whenever there is original discharge. When the child is born it should have its eyes wiped immediately with absorbent cotton and then washed with boiled warm water. The use of antiseptics is not advised except in those cases in which the vaginal secretion of the mother contains gonococci. Or to insure greater safety a solution of formal 1 to 1000 may be used daily, as it is not irritating and has both an antiseptic and anesthetic action.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 FIFTH AVENUE, NEW YORK.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, JULY 8, 1899.

THE BUBONIC PLAGUE AND OUR WESTERN COAST.

WE quoted some time ago from the *Indian Medical Record* the editorial opinion that Bombay and Calcutta were doomed cities, because of the practical impossibility of ever getting their sanitary conditions into reasonably good shape. It is evident then that the present danger to the civilized world from plague is to continue for some time, and that it is not so much special precautions against incidental exposure, because of a single infected vessel, as a thorough system of quarantine against certain Eastern ports that is needed The conditions that have developed for the United States in the Far East during the last year emphasize the necessity for a complete and uniform system of quarantine on our Western Coast. Our commercial intercourse with the East is assuming much more importance than before. The annexation of Hawaii gives us another and most vulnerable point in the matter of public health and the importation of disease.

The work of the Marine Hospital Service has so far been effectual, and its service can be depended on to institute effectual quarantine wherever its powers and facilities are adequate. With our extensive Western coast line, however, under the new conditions that are coming in, the lack of uniformity in quarantine regulations may constitute a serious source of danger. That good quarantine regulations can be effective British colonial history for the last four years proves. Despite the existence of the plague at a number of important points along the lines of colonial commerce the British Government has been able to prevent its spread from the originally infected districts. The successful international quarantine of the Red-Sea district and of the Suez Canal has been especially deserving of applause and has shown how much can be accomplished by modern sanitary science in the face of the most serious difficulties if it is but given the opportunity.

The problems involved in our own quarantine regulations, East and West, against yellow fever and the plague, make evident the necessity of some central authority clothed with plenary power and uniform regulations to take complete charge of both our seaboards so as to effectually guard the country's health. The American Medical Association at its recent meeting voiced the sentiment of the medical profession of the country in formally counselling the establishment of a National Department of Public Health, to be presided over by a member of the President's Cabinet. As our commercial relations become more extensive this becomes more and more a necessity. Let us hope that its advent will not be delayed ununtil some epidemic makes fatally plain the lesson that is so patent already.

CEREBROSPINAL MENINGITIS AS A PANDEMIC DISEASE.

As we noted editorially at the time, the discussion of cerebrospinal meningitis at the recent meeting of the American Medical Association at Columbus brought out especially the fact that the disease is much commoner here in America than is generally supposed or the text-books seem to teach. But practically the same thing appears to be true all over the world. The crowding together of soldiers in this country under especially unhygienic conditions during the recent war led to an outbreak of the disease as an epidemic in several of the camps. During the late Turco-Grecian War reports of the same

tenor came from both armies. At Omdurman and Khartoum the British soldiers suffered in a similar way, and the epidemic at Omdurman was especially severe and fatal.

It would seem then that the germs of the disease are practically universally present, and that only a favorable opportunity is necessary, as when resistive vitality is low, to give the disease a suitable nidus. And after its passage through a series of susceptible organisms it takes on a virulence that makes it fatally epidemic in character. Its manner of transmission remains as yet a mystery. During the present year we have had reports of the disease as an epidemic in various parts of the country, especially in the middle West and South, and our Philadelphia correspondent quotes from the Pennsylvania State Board of Health reports the statement that there were in the city of Philadelphia during the month of May twenty-two cases of cerebrospinal meningitis with fourteen deaths. The subject of the frequency of the disease and its mode of transmission evidently demand careful investigation.

The affection has of late acquired additional interest from the announcement by Professor Schultze of Bonn (*Muenchener Medicinische Wochenschrift*) that, in a case of typical anterior poliomyelitis in which the subsequent course of the case—the atrophy of muscles, etc., had confirmed the original diagnosis, lumbar puncture disclosed in the cerebrospinal fluid the presence only of the meningococcus intracellularis—the micro-organism that Weichselbaum demonstrated to be always present in fatal cases of cerebrospinal meningitis and which is generally accepted now as the cause of that disease. If it should prove that anterior poliomyelitis in only certain cases is really a mild cerebrospinal meningitis (we have realized for some time that it is some form of acute infectious disease) it will greatly add to the interest of both affections.

The sporadic cases of anterior poliomyelitis that occur with such comparative frequency and over so wide an extent of territory may help to explain how cerebrospinal meningitis is kept in existence and how its transmission occurs so insidiously. It would throw light too on the sudden and apparently unaccountable outbursts of the disease by recognizing that its passage through a series of susceptible organisms has suddenly given it increased virulence.

IS IT PROPER FOR A PHYSICIAN TO EMPLOY A PATENTED DRUG?

In discussing this question, it is necessary to clearly define at the outset what is meant by a "patented" preparation. Patent medicines, so called, are not as a rule patented but are protected by being accorded a copyright of the name and by the customary use of that name as a trade-mark. Strictly speaking, a patent medicine is one which is made by a patented process, which process has been devised as the result of thought or experimental research, and is quite as much entitled to Governmental protection as is the result of the thought or experimental research which ends in the invention of any machine which is of distinct benefit to the human race. If the general theory of patents is correct, that the inventor of industrial articles is entitled to the sole benefit of his ingenuity for a certain period of years, the chemist is equally entitled to similar reward, as by reason of his skill he has produced a drug which is of distinct value to his fellow men.

The term chemist or druggist here is used advisedly, in distinction from the term physician, because it is generally held that the higher ethics of the medical profession does not permit its members to patent remedial drugs or instruments. We are therefore not in favor of physicians patenting the results of their genius, but the question before us is whether a physician shall use substances which have been patented by persons outside the bounds of the medical profession.

It seems to us that this question should be answered unquestionably in the affirmative, first, because many of these substances are of very decided value and, therefore, it is to the interest of the profession to use them, and secondly, because the physician has no right to deprive his patients of chemical products which he knows are specially indicated simply because he does not approve of the methods by which they are manufactured or protected. By force of circumstances, physicians have within the last few years continually prescribed remedies which are patented, as antipyrin. But the patents on antipyrin have expired, and the profession and laity are now enjoying at the simple cost of manufacture and distribution the benefits of the chemist's skill and labor without depriving him of the just reward that is universally granted to inventive genius.

There is a class of preparations which we believe physicians should carefully avoid using, namely, medicinal substances advertised to the laity. These should be avoided not from the business standpoint that they deprive the profession of practice, for this they do not do, because patients who take these preparations usually do so with such disastrous effects that the profession is pecuniarily benefited in the end by acute cases being transferred into chronic ones, but because the advertisement of these preparations to the laity causes non-medical readers to dose themselves with compounds which in many cases are not only useless but distinctly harmful. The products of those manufacturers who sell a preparation to the medical profession with the right hand and the same preparation to the laity with the left, should also be carefully avoided in writing prescriptions.

ECHOES AND NEWS.

Diplomas Given to Nurses.—The Training School for Nurses of the Manhattan State Hospital on Ward's Island held its second annual graduation exercises on June 14th. There were 110 graduates, of whom 69 were women.

Dr. Austin Flint, President.—Dr. Austin Flint was elected President of the Medical Association of the Greater City of New York, which held its stated monthly meeting at the Fifth Avenue Hotel in New York on June 12th.

Increased Hospital Accommodations in Paris.—The Municipal Council of Paris is considering an expenditure of 72,000,000 francs for the erection of additional hospital accommodations. This amount of money would be sufficient to provide 2810 new beds.

Post-Graduate Medical School.—The eighteenth annual announcement of the New York Post-Graduate Medical School shows that 523 Doctors in Medicine from 57 States, Territories and countries, have attended its courses during the year ending June 1, 1899.

Wedding Gift to Hospitals.—Mr. Arthur P. Heinze of Brooklyn and Miss Ruth Noyes of Butte, Montana, were married in the latter city on June 15th. After the ceremony Mr. Heinze and his brother gave $5000 each for the establishment of emergency hospitals in Butte.

Spurious Sanatorium Raided.—The house at 9 East Twenty-seventh street has been raided as a disorderly house. For the past year a woman calling herself Dr. Frances McCullough has conducted there what she termed a sanatorium. All the women were dressed as nurses.

Fifty Ambulances Missing.—Fifty hospital ambulances, which were shipped from Chicago to Tampa, Florida, more than a year ago by the local army officials to be forwarded to Cuba for the use of the United States troops on the island have been lost. Thus far there has been no clue to the missing property.

The Seaside Hospital.—The new building of the Seaside Hospital at New Dorp, Staten Island, was dedicated on June 16th to the work for which it was erected by St. John's Guild. The new building, which is an addition to the old one, is a four-story brick fireproof structure, and is fitted with the best modern sanitary appliances. Last year 2057 patients were treated at New Dorp.

Expectoration in Hoboken.—Hoboken is setting a good example. An anti-spitting ordinance is being enforced in that city. Policemen are ordered to warn those who spit and to arrest upon a repetition of the act. There is a fine of $10 for the first offense and of $25 for a second offense. Spitting is prohibited in all public places except into cuspidors, which are furnished by the city.

The Destitute Blind Relieved.—$35,000 in gold was distributed among 700 blind men and women at the office of the Department of Charities of New York City on June 13th. By a provision of the charter $75,000 is appropriated for yearly distribution to the destitute blind of the city. The remaining $30,000 will be distributed among the blind poor of Greater New York outside the Borough of Manhattan.

Typhoid along the Ohio.—It was reported from Wheeling, West Virginia, on June 13th, that typhoid fever is epidemic in many of the towns along the Ohio River from Pittsburg to Cincinnati. Its prevalence is attributed to the deleterious conditions produced by the big flood of last spring. It is noteworthy that towns having water-supplies far removed from the river have fared no better than communities which depend solely upon the muddy and filthy water of the Ohio.

A New Cancer Hospital.—On June 19th there was established in Perry street near Greenwich avenue in New York City a branch of the French Catholic Charity known as the "Women of Calvary" for the gratuitous treatment of indigent female cancer patients. The first House of Calvary was founded in Lyons in 1842, and in 1874 there was another established in Paris; another in Saint Etienne soon followed, and in 1881 a fourth in Marseilles. In 1886 a house was opened in Brussels, Belgium, and in 1892 another was founded in Rouen.

The Working of England's Inebriate Act.—An attempt has been made recently to get a woman of North London committed to a drink-cure establishment, under the provisions of the Inebriate Act, which went into effect at the beginning of this year. It was shown that the woman had been convicted of drunkenness five times this year, but the magistrate refused to grant the request on the grounds that the act referred to respectable women who had fallen victims to the craving for drink, while the prisoner did not seem to him to be of that class. The case will be appealed.

No Bubonic Plague at San Francisco.—Dr. Wyman, surgeon general of the Marine Hospital Service, denies the existence of bubonic plague on the ship "Nippur Maru," in the harbor of San Francisco, as reported in the daily press. The two Japanese who jumped overboard from the ship were stowaways who connived with members of the ship's crew to escape, and were drowned in trying to evade the customs patrol which had been established around the vessel. They were strong men, and free from disease. The members of the crew and the passengers are all well.

The Passing of Homeopathy.—Under the above title the *Cleveland Journal of Medicine* records the fact that no less than fifteen homeopathic practitioners of that city, after having spent the winter in study at the Cleveland College of Physicians and Surgeons (regular) have received the degree of M. D. An equal number had previously done so, so that in Cleveland at least there seems some reason to justify the title to the item above given. The editor commends to the consideration of their professional brethren these men who have had the honesty to give up false claims at the cost of no little personal trouble and expense.

Yellow Fever.—The Marine Hospital Service reports that from May 6th to 19th there were, at Rio de Janeiro, thirty-four cases and seventeenth deaths; at Havana, June 8th to 15th, one death; at Matanzas, June 30th, one case. Ten cases were reported among the troops of the garrison at Santiago on July 1st, five cases July 2d, and five cases July 4th. There have been thus far seventy-nine cases of the disease there and fifteen deaths. The quarantine against the troops is very strict. No soldiers are allowed in the city except a small guard about the arsenal. There are no cases among the civilians.

Tests upon Tuberculous Cows —Experiments upon tuberculous cows which have been conducted at the Ohio Experiment Station throws some doubt on the correctness of the theory that tuberculosis is communicated by the use of the milk of consumptive cows. Two years ago eleven cows were condemned by the tuberculin test. They were segregated, but in no other respect was any change made in their care. Their milk was fed to calves one of which, after having been thus nourished for seven months, showed no reaction with tuberculin, and no tubercles were found post-mortem. The eleven cows were slaughtered recently, and the government inspector condemned the carcasses of only two of them as being unfit for food.

The Case against Dr. Cleaveland.—At the preliminary hearing on the third charge (two previous indictments having been dismissed for want of evidence) against Dr. Trumbull W. Cleaveland, which was held before Magistrate Wentworth on June 14th, Bartow S. Weeks, Esq., counsel for Dr. Cleaveland, read a long itemized bill for the Carhart baby's funeral expenses, which he said had been sent to Dr. Cleaveland for payment. The bill footed up to $727.60. Among a great many items were the following: Mourning for Mrs. Carhart, $35, mourning for Mr. Carhart, $15, mourning cards and stationery, $3, stone $166, care of grave, $1, photographs of baby after death, $20, vocal music at funeral, $20, organist, $20, sexton, $10, a stateroom on Fall River boat, $2, etc., etc. This looks extremely like a case of malicious prosecution. It is not surprising that the case, as announced in our last week's issue, was promptly dismissed.

The Pestilential "Christian Science."—The lay press daily reports cases of death and misfortune which are due to the presence among us of this pernicious cult. The evil is becoming so great that in order to correct it some other means will have to be employed than mere ridicule which usually suffices to kill movements akin to this, such as have originated either in abnormal mental processes, or in the deliberate purpose of their originators to humbug humanity. At Elgin, there died in the Illinois Northern Hospital for the Insane, on June 18th, Ellen L. Gilson. In this institution were also Gertrude, the daughter of the deceased, and Elmer E. Day, the brother of the deceased. All lost their reason through the study of Christian Science. At Minneapolis, Minn., on June 20th William E. Bradford died without medical attendance. He had been ill since June 1st. Christian Scientists had "treated" him. Miss Eva Banfield, a Christian Scientist, was sent to the Buffalo State Hospital on June 22th, having become insane. Joseph Caig died in Philadelphia on June 22d of "heart disease," so the autopsy showed. He had had no physician. A Christian Scientist was his "healer." At Falls City, Nebraska, the three-year-old child of George Sperry became ill. The mother, a believer in "divine healing," would not permit a doctor to be called. The child having rapidly became worse the father pleaded with a physician to treat it. This was done and the child grew better, and was on the road to recovery. One night the physician's son remained with the child and it was only by force that he administered to it, the "healers" swarming about him all the while, and saying everything he did was instigated by the devil. When the doctor left the next morning they threw the medicine away, locked the father in the kitchen, and prayed over the child until it died. This was on June 22d. Mrs. Porcella of Cranford, New Jersey, died on June 22d. A year ago she became a Christian Scientist. Shortly after this she contracted a severe cold, which she paid no attention to. Then phthisis appeared. But she would not be treated by medical men until three weeks ago. Thus does the ghastly procession pass before us. It is pleasing to be able to record that some steps are being taken to restrain this evil. At a meeting of the Medico-Legal Society of New York on June 21st the President was authorized to appoint a committee, whose duty it shall be to investigate the methods of the "Christian Science healers." In Philadelphia also something is being done by the County Medical Society whose President, Dr. Solis Cohen, considers that "important issues in public health are involved which give the State the right to interfere in order to protect children and other helpless persons from their parents or guardians. Moreover, these issues give the State the right to interfere to protect the community from contagious diseases which

may spread if not properly treated and do much harm to the community."

Distinguished Medical Visitors to America.—In the decennial celebration of Clarke University, Worcester, Mass., which commenced July 5th, two distinguished foreign medical men have taken part—Professor Santiago Ramon y Cajal of the University of Madrid, Spain, and Professor Angelo Masso of the University of Turin, Italy. Professor Ramon y Cajal will be recognized by American medical men generally as the well-known investigator into minute nervous anatomy, whose work during the last ten years has attracted world-wide attention. He is practically the only Spanish member of the medical profession whose work is known outside of the confines of Spain, and almost the only Spanish scientist who in our generation has made in any line distinct contributions to scientific knowledge. His work met with little encouragement in university circles in Spain itself until the interest of the outside world in it compelled its recognition. Professor Ramon y Cajal has gathered around him at Madrid a corps of workers in minute anatomy, and especially in the normal and pathological histology of the nervous system, all of whose contributions are now eagerly awaited, and the results noted by all other workers in these lines. Professor Angelo Masso is best known perhaps for his work in recent years upon the ductless glands, and especially upon the interesting questions involved in the parathyroid glands and their relation to the thyroid and to the general nutrition and metabolic processes of the organism. A discussion carried on through the medical journals for some time with Professor Gley of the Sorbonne on this subject brought him into a good deal of prominence a few years ago. It is to be hoped that both these distinguished medical visitors will meet with a suitable welcome from the profession wherever they visit in this country.

CORRESPONDENCE.

THE AMERICAN MEDICAL STUDENT ABROAD.

MEDICAL STUDY AT THE SMALLER GERMAN UNIVERSITIES.

FOR most medical men medical study in Germany means courses taken at Berlin or Vienna, or perhaps, Munich or Leipzig. Too often it is forgotten that the younger and more pushing men, the men with a present and a future in medicine, though perhaps not yet with a past, are as a rule doing their work in the small German university towns. Of course the younger men have not as yet won that reputation across the sea that the attainments of older men have brought to them, but instead of resting on their oars in a very proper elderly conservatism they are pushing their way in the very forefront of medical advance; they are doing the work that will later put them at the head of clinics and departments in Vienna and Berlin and Leipzig and Munich, while just now they are in that precious stage of youthful enthusiasm for progress and discovery that makes personal contact with them an incentive to original work such as can be imparted in no other way.

It is to be remembered that advancement very seldom comes to the German assistant professor at the university where he spends his early years of teaching. He must have had some years of experience in charge of a clinic or institute at one of the smaller universities; he must have shown his prowess of initiative and his capacity for independent work before he will be called to a chair in one of the large universities. The present professors at Berlin and Vienna, for instance, have, with very few exceptions, passed through a preparatory novitiate at more than one smaller university before their call to the large cities. Professor von Leyden was at Königsburg and Strasburg, Professor Gerhardt at Jena and Wurzburg, Professor König at Göttingen, Professor Nothnagel of Vienna after being assistant at Berlin was at Jena we believe, Professor Gussenbauer was at Prague. It is well understood by the assistants at the large clinics that direct promotion at a great university is practically out of the question. "Unless" as one of them once said to me, "I should turn the medical world half upside down." The young men accept the full or ordinary professorships at the smaller universities, though as a rule the salary is not a very tempting one, because they fully appreciate that this is the next and essential step in their career as university professors.

It is the work being done by these younger men particularly that is keeping German medicine in the van of medical progress. Contact with them is a precious thing and should constitute a part of the prospect to every young American going abroad. Of course the work in the smaller university towns has its drawbacks because of the small amount of clinical and pathological material that there is to work with. It may readily be imagined that Jena with about 10,000 people, Marburg with 15,000, or Griefswald with something less than 25,000 cannot furnish the variety of cases, the multiform complications and sequelæ, and the anomalous pathological conditions that would be desirable for purposes of university and especially post-graduate study. It must be remembered, however, that practically all of the poorer classes, who represent a much larger proportion of the population than here in America, are treated at the hospitals and in the university dispensaries; that the reputation of professors brings material from the neighboring country side, and that certain arrangements are made to supply hiatuses in pathological material by the university authorities from larger centers.

The principal advantage to be derived from attendance at the smaller universities is that personal attention is secured in whatever the student undertakes, and if the worker or investigator be but serious in his labors nothing seems too much to do for him. The contrast in this regard from the spirit of indifference or perfunctory fulfilment of duty that has been paid for which so often characterizes the attitude of clinical assistants and others engaged in work with Americans at the larger universities is most notable. For the theoretic branches especially, for pathological anatomy, for physiology, for bacteriology,

and the like the smaller universities are in a position to give much more thorough and satisfactory courses to those who really seek a thorough knowledge of certain subjects in medicine and not a hasty superficial glance at everything medical knowable and a few other things besides.

Additional advantages at the smaller universities are that the absence of large numbers of Americans with whom in the larger cities the student is continually thrown in contact enables him to pick up German much sooner and better. Constant association with Germans forces the knowledge of the language upon him in less than half the time that the student in the larger cities requires unless he is eternally vigilant in grasping opportunities. Another advantage and one not to be despised is the knowledge the student gets of real German university life and of the German university town as such. Large cities are unmaking the old university life all over the world and it is becoming harder and harder to understand certain historical details that German university towns still preserve. To one who is interested in German national life (and what doctor is not interested in knowing the people as they are) life in a small town will give certain true impressions of the genuine national life of the people that cannot be obtained in a large city. All the large cities of the world are being recast in the modern mold of practical municipal advancement which is rapidly doing away with all that is characteristic in them, and the people are being modified by their environment. The true spirit of advance has not yet touched the smaller towns or only enough in passing to make them sanitary dwelling places without interfering too much with their interesting natural conditions.

After this rather long prelude I may add a word or two of some of the smaller German universities at which I have had a brief personal experience, sufficiently recent for my impressions of them to be of practical service to others perhaps who may contemplate a European medical pilgrimage in the near future.

Bonn is beautifully situated just on the most picturesque part of the lower Rhine, below the Siebengebirge, the famous scenic seven mountains and is *the* fashionable one of the German universities. To Bonn the present Emperor went as a student and many of the sons of the German nobility go there for part of their course at least. The opportunities for work are excellent and the material (Bonn has some 50,000 inhabitants) reasonably plentiful. Schultze in medicine, Schede in surgery, and Pellman in mental and nervous diseases are all well and widely known. They are not young men but they have associated with them some excellent assistants and are themselves not beyond their days of enthusiastic investigation. Bonn has the disadvantage from one point of view of having a good many English and American visitors during the summer semester, but is a delightful place in which to stay.

Griefswald in the distant north not far from the Baltic Sea is a very charming old town, whose university, owing to the rivalry with the University of Rostock in the duchy of Mecklenburg-Schwerin, is kept at a very high standard by the special efforts of the Prussian Government, which takes this means (and a very good one it is) of demonstrating the advantage of living under Prussian rule. In the faculty are Löffler, Grawitz, who is prominently mentioned as the prospective successor of Virchow at Berlin, Mosler in clinical medicine, and Landois the physiologist, whose text-book is so well known in this country. I do not know of any place where a summer semester of investigation or experimental work in one of the theoretic subjects with occasional excursions into practical medicine could be passed more pleasantly than here on the cool pleasant shores of the Baltic Sea.

Heidelberg is, if possible, more beautifully situated on the upper Rhine than Bonn lower down. Around it cluster some of the most characteristic traditions of German university life, and the German student, with all his oddities, the only ones we are apt to consider at a distance, and his many excellent and admirable qualities which only intimate association with him brings out, may be seen to better advantage here than anywhere else. Erb and Czerny are here, which is enough to say from a medical standpoint, but there are others.

Jena is one of the old German universities not so noted for medical as for other work but where excellent opportunities are given. Stintzing in medicine, known especially for his work in therapeutics, Riedel who has made a name recently in surgery of the biliary tracts, Binswanger in mental and nervous diseases, and Ziehen in physiological and pathological psychology are here.

There is an air about Jena in its picturesque location, in the midst of its traditions, in the pretty old university town as yet unspoiled by any, even the slightest, tincture of progressive modernity that makes a stay there most interesting.

Marburg is another university town that is most beautifully situated. These four: Bonn, Heidelberg, Jena, and Marburg do not suffer by comparison with one another as far as regards picturesque situation. The two first are better known to the tourist because of their situation on the Rhine, but personally I should not care to have to make the choice from their scenic advantages alone. Marburg like Greifswald has been especially well cared for because of its nearness to a rival university, Giessen in the duchy of Hesse. It has a magnificent set of new university buildings and especially an entirely new set of medical clinics. Mannkopf is here in medicine, Küster, whose work especially in renal surgery has brought him into prominence of late, is in charge of the surgical clinic. Frederick Muller is here as an extraordinary professor in medicine, Behring is here and has besides the university laboratory in the town a magnificent private laboratory most beautifully situated on the heights above the town. The whole faculty at Marburg is far above the average. The salaries paid professors are higher than those at other universities because of certain funds that come to the Prussian Government and certain obligations it assumed in the matter of university and public education when it deposed the reigning duke and took up the ruling power in 1866.

The German university at Prague can scarcely be

called one of the smaller German universities despite its scant 300 medical students. There is no dearth of material for clinical and pathological work. Of the infectious diseases generally, even smallpox, of contagious skin diseases or those due to dirt and neglect; of the varied complications of disease due to lack of sanitary arrangements Prague has a most abundant supply. Great improvements in sanitation have been made in recent years, but a large field for clinical work in the branches that depend for their material on defective sanitation still remains. From the well known character of the professors at Prague it seems needless to add that excellent advantage is taken of the material so amply provided. Von Jaksch and Pribraam in medicine, Wölfler in surgery, Pawlik in gynecology, Ganghofner in children's diseases, Chiari in pathology, the two Picks, one in dermatology the other in neurology and mental diseases are all names to conjure with in the medical world. Of course Prague has for years been noted for its excellent teaching in obstetrics and still retains her reputation in this respect. On the whole the opportunities for study at Prague are excellent and are not taken advantage of as much as they would be if the conditions were known better abroad.

I have mentioned somewhat in detail these six German universities because of personal familiarity with them. By reputation one gets to know in Germany certain other universities that present some good opportunities. Breslau, where the rivalry with the Austrian universities has led the Prussian Government to devote a good deal of money and energy to the making of an excellent university in all departments and many of whose professors are among the best known in German medicine. The University of Göttingen of other fame than medical but where Orth, who is also prominently mentioned as Virchow's possible successor, is doing some excellent work in pathology; Strasburg, where Von Recklinghausen's work in pathology is well known, Naunyn is doing some of the best clinical and experimental work in Europe, and Minkowsky's physiological observations are eagerly looked for by the medical world. No effort has been spared by the German Imperial Government to give the new German university that succeeded the French university one of the best teaching faculties in Europe, and a teaching plant second to none. In this, as in everything else that Germany has seriously undertaken of late years, it has succeeded admirably.

I fear that my catalogue of the minor German universities has extended itself until it has lost its value as counsel and become a mere list. Very few German medical students, however, limit their studies to two universities, but spend at least a semester at three or four. The plan has its advantages in the breadth of view it gives as to the comparative value of certain lines of medical advance. It would certainly be of distinct benefit to Americans not to limit themselves to any one school of teaching. Attendance at several universities demands several years abroad, however, and the American student is apt to go with the idea that he can absorb all that he will care to in a year or less. The sooner this notion is abandoned the better.

The Americans and Englishmen whose foreign studies have been of special service to them, of whom the late Professor Kanthack of Cambridge, and our own Professor Welch of Johns Hopkins are notable examples, have all spent considerable time at patient investigation, usually in one definite line and without spending themselves on a number of subjects. It is this readiness to devote sufficient time and care to medical investigation that constitutes, as I called attention to once before in the MEDICAL NEWS, the essence of the good work done by the Japanese medical students in Europe. When the younger American medical students are ready to devote themselves in the same way to patient clinical or experimental work not for one, but for two or more years, they will return after their European experience much better fitted to take up the work of advancing scientific medicine in America than now, when application to too many supposedly practical subjects gives but a superficial knowledge of many things that are not long of benefit to the rising medical man.

JAMES J. WALSH, M.D.
1973 SEVENTH AVENUE, NEW YORK CITY.

BLOODLESS TONSILLOTOMY.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—For quite a number of years I have been very interested in the excision of tonsils, and in reading the article by Dr. Dawbarn, in the MEDICAL NEWS of May 20th, thought that his idea a good one. Although I have never had a severe case of hemorrhage from a tonsillotomy I have always expected it, as I find the tonsils in children, as a rule, do not bleed much and are devoid of blood-vessels. I avoid taking out tonsils in adults as much as possible, especially if they are hard, and always examine with my finger to find out whether there is any anomalous condition of the arteries. Dr. Dawbarn's article, entitled "Bloodless Tonsillotomy," in the MEDICAL NEWS of June 10th, is a thing not entirely to be desired, as I think the local blood-letting that comes from tonsillotomy is a part of the good which is derived from the operation, and which you also get from the operation on the tonsil of Luschka, or on adenoids, and when I have very little bleeding I frequently use a little friction to bring it about. The mouth-breather, or the child with chronic hypertrophied tonsils, is the patient that gives the throat and nose specialist the most trouble to-day, and when the physician can relieve the patient he receives the thanks of the parents.

Yours truly,

CARR LANE, M.D.

ST. LOUIS, June 24, 1899.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

ILLINOIS SOCIETY FOR THE PREVENTION OF CONSUMPTION—STATE BOARD OF HEALTH MATTERS—ANNUAL MEETING OF THE CHICAGO MEDICAL SOCIETY.

CHICAGO, July 3, 1899.

A MEETING of prominent physicians and laymen was held June 20, 1899, in the Hall of the Chicago Medical

Society, and the organization of the Illinois Society for the Prevention of Consumption was effected. Several speeches were made in which measures both for the prevention and extermination of the disease were discussed. Dr. L. G. Marillat, speaking on behalf of the Chicago Veterinary Society, presented a summary of the points which he said could be easily demonstrated: (1) That the tuberculin-test for bovine tuberculosis is sufficiently reliable to be practical. (2) That the sale of milk from tubercul us cattle should be absolutely prohibited, and that the apparent absence of tuberculous processes in the mammæ of a cow is no assurance of non-infectious milk. (3) That tuberculosis is raging among the dairies of Chicago and vicinity, and the people of Chicago are actually being infected with tuberculosis through its milk-supply. (4) That proper veterinary inspection of dairies will eventually result in purifying the supply, and such inspection should be conducted under the direction of the Commissioner of Health of Chicago, who in turn should collaborate with the State officers in their efforts to exterminate the disease from domestic animals. Dr. A. S. Alexander said that in order to insure absolutely wholesome, pure, innocuous milk we must have, first, a perfectly healthy, clean cow. Second, she must be fed on perfect, sound, sweet, nutritious food. Third, she must drink uncontaminated water. Fourth, she must be surrounded by a perfect sanitary environment and housed in a fine stable. Fifth, the milk so produced must be protected against secondary infection. Tuberculosis may be eradicated from any stable by the proper use of tuberculin. Dr. William A. Evans discussed the mortality of tuberculosis and gave the annual mortality statistics from this disease in the large cities of the world. The following officers were elected: Honorary president, Dr. N. S. Davis, Sr.; president, Mr. John MacLaren; first vice-president, Dr. William A. Evans; second vice-president, Dr. Edwin Klebs; third vice-president, Dr. A. H. Baker; secretary, Dr. John A. Robison; treasurer, Mr. Elbridge G. Keith

The efforts of the Society with regard to legislative action will be: To urge the State Legislature to appropriate a fund adequate to the needs of the State Board of Live Stock Commissioners, this sum to be probably $50,000 for the first year, $30,000 the second, and $20,000 the third. To insist that the Legislature increase the executive force of the Live Stock Commission sufficiently to enable the Commission properly to fulfil its duties. To urge that the Commission be empowered to administer the tuberculin-test to all cattle in the State without the consent, or if necessary, against the wishes of owners of cattle. To make it necessary that the Commission begin a systematic examination of all cattle in the State, and all cattle not proving under the tuberculin-test to be free from tuberculosis shall be condemned, and the owners compensated by the State at the scale of prices fixed by the Live Stock Commissioners. To devise and recommend an efficacious plan for the prevention of the sale of tuberculous milk in Chicago; this plan modeled for the most part after the method adopted by Buffalo; to recommend that the Common Council enact an ordinance creating a force of experts in veterinary medicine, whose duty it shall be regularly to inspect the dairies supplying milk to the Chicago market, whether or not such dairies be within the city limits; and the plan further to provide that no can of milk shall enter the milk depots of Chicago without a number corresponding with a number on the sanitary report of the dairy from which the milk was shipped.

The State Board of Health, at its meeting held in this city recently, adopted resolutions calling on the Legislature to vest the Board of Live Stock Commissioners with authority to conduct sweeping investigations looking to the eradication of tuberculosis in cattle and to grant a special appropriation for the work. The Board voted that Illinois municipalities ought to pass ordinances prohibiting the sale of milk from untested herds. The Board revoked the practising licenses of H. E. Colby and William F. Hughes

In the slaughtering of condemned cattle by the Live Stock Commissioners on June 18th out of 91 cattle slaughtered, 89 were found to be infected with tuberculosis, and 57 were so badly affected that the carcasses were condemned.

At the annual meeting of the Chicago Medical Society, held June 21, 1899, the president, Dr. Arthur D. Bevan, delivered an address on "The Science of Medicine and Its Relations to the Public." He said there is a science of medicine just as truly as there is a science of chemistry or of astronomy or anatomy. Just as chemistry is dependent on physics and mathematics, so medicine is dependent on chemistry, physiology, pathology, and anatomy. Medicine does not hesitate to borrow from any branch of knowledge that may aid in its development, and it follows that as these aiding sciences develop, medicine will advance. Medicine must let the world know that it begins the twentieth century as a pure science, and that it has left behind it the mystery, the superstition, the dogmas of the past. The teaching of medicine must be in the hands of scientists. Students of medicine must be taught its truths and limitations. The public, with its ever growing ability to grasp knowledge, must be taught its truths and frankly told of its limitations. He then discussed the great duty which the science of medicine owes to the public under four heads: First, by developing and teaching the science and practice of medicine along purely scientific lines. Second, by demanding a high standard of knowledge and efficiency of men desiring to practise medicine. Third, by educating the public in the great truths of medical science. Fourth, by obtaining national, State, and municipal recognition of the great medical truths which can be incorporated into laws for the good of the community. Of twenty medical colleges in Chicago, he said possibly there were three sufficiently well conducted to warrant their recognition as scientific schools; the others have no right to such a claim. They represent either some paltry or a pathologic desire of a group of men for the title of professor and the opportunity to advance and advertise themselves. This results in the turning out of poorly equipped medical men and the lowering of physicians generally in the eyes of the public. Modern medicine demands a scientific train-

ing. The modern medical school must drill its students in the sciences of anatomy, physiology, pathology, chemistry, and pharmacology in well equipped laboratories. These laboratories must be not only teaching mediums, but workshops for the discovery of new truths. After this preliminary work the student will study medicine, surgery, obstetrics, and the specialties in well-equipped hospitals and dispensaries. He would like to see a national law to control medical practice, although it seems an insurmountable task to obtain it.

When we see the good accomplished by vaccination, by quarantine against yellow fever and cholera, by antitoxin in diphtheria, the lessening of typhoid by pure water-supply, the elimination of trichinosis by inspection of hog products, as done in Germany, and now the great awakening in regard to the prevention of tuberculosis, one must be impressed with the tremendous possibilities of preventive medicine. The realization of these possibilities depends upon the education of the people as to the dangers of disease, the cause of disease, and the practical method of prevention.

The following officers were elected: President, Dr. Junius C. Hoag; vice-presidents, Drs. Henry B. Favill and Hugh T. Patrick; secretary, Dr. Arthur R. Edwards; treasurer, Dr. S. C. Plummer.

OUR PHILADELPHIA LETTER

[From Our Special Correspondent.]

ANOTHER LEGAL SET-BACK FOR THE ANTIVACCINATIONISTS — THE "KISSING-BUG" EPIDEMIC — THE SALE OF "EMBALMED" MILK — DIPHTHERIA AND THE FACTORY INSPECTORS — TUBERCULOSIS IN CATTLE — MEDICAL SOCIETY OF NEW JERSEY — SMALLPOX IN PENNSYLVANIA.

PHILADELPHIA, July 3, 1899.

STILL again has the antivaccinationist resorted to the courts to contest the constitutionality of the compulsory vaccination law, as applied to public-school pupils, and again has the opinion of the law defeated his intentions. The petition of a Mr. Charles J. Field of this city, aimed against the vaccination law as it now exists here, has been defeated, and the outcome gives satisfaction to every citizen of intelligence, lay and professional. The complainant filed a petition requiring reason to be shown why his daughter should not be admitted to a public school by its principal, who had refused to admit her because she failed to produce the proper certificate from a physician showing that she had either been successfully vaccinated or that she had at one time suffered from smallpox. In answer to the petition the City Solicitor filed an answer upholding the principal of the school, stating that the defendant was compelled to comply with the law passed in 1895 relating to this question, and further, that the principal had to comply with a similar rule of the Board of Education. Thus another attempt to overthrow the compulsory vaccination law has been defeated in its incipiency, as has been the fate of all such attempts against this established prophylactic measure. But the incident proves that primitive mental receptivity still prevails in some quarters, and that lovers of right and of enlightenment must be on their guard to abort these attacks upon common sense, proven safeguards of the community's health.

That annoying insect popularly known as the "kissing-bug," which has been epidemic recently in Washington and Brooklyn, has visited Philadelphia, in the course of its peregrinations northward, its presence here having become very evident by reason of the dozens of persons who have suffered from its bite during the past three or four days. The bites of this insect, which usually occur on the lips of the individual attacked—hence the name, "kissing-bug"—are quickly followed by extensive swelling of the part, which becomes red and inflamed, and exceedingly sensitive. Signs of active cellulitis are often present, and the lips swell to two or three times their normal size, so that articulation and eating may be impossible. The process subsides rapidly after forty-eight to seventy-two-hours' duration. The exact identity of the insect concerned in this epidemic is somewhat in doubt, but it is thought to be one of the varieties of the so called "assassin bugs," probably the opiscoetus personatus, which is a common parasite of the ordinary bedbug and house-fly. It is an insect nearly an inch in length, of dark, brownish-red color, and having six legs and long antennæ. During the past week more than a dozen persons have applied for hospital treatment on account of its bites, and according to current reports the list of its victims continues to increase from day to day.

"Embalmed milk," as it has been termed by those of facetious turn of mind is just now giving the inspectors of the Board of Health all sorts of worry, and extensive searches and tests are being carried on, to detect the presence and to suppress the use of this deleterious preparation. "Embalmed milk" is nothing more nor less than milk to which formaldehyd has been added to prevent souring, and it is claimed that its use is fast becoming general, particularly in the poorer sections of the city, among dealers with whom cheapness, and not quality, is the prime object of trade. The very minute proportion of formaldehyd required to prevent fermentation of milk, and the difficulty with which it may be detected by the ordinary methods employed in milk-testing make its detection a rather elaborate chemical analysis, and decrease the chances of its being suppressed. Philadelphia has recently had quite an extensive assortment of other food adulterations, in addition to this form, the authorities having brought to notice a number of other instances relating to the adulteration of coffee, vinegar, and cider. What with fever-germed Schuylkill water and formaldehyded milk and salicylated beer, the poor inhabitant must needs altogether abandon liquid indulgences unless his immunity happens to be absolute.

The discovery this week of diphtheria in a "sweat-shop," by one of the State factory inspectors, is a rather disturbing incident which calls for increased vigilance and thoroughness in the inspection of premises where clothing and other articles of general sale are manufactured. Thanks to a new law, the authorities were able to take prompt and radical measures in the present instance, by seizing and confiscating all the clothing found in the

place. By the present plan of cooperation between the factory inspectors and the health-office of this city, it is believed that the dangers of the spread of infectious diseases from such foci will be at once minimized.

Dr. Leonard Pearson, the State Veterinarian, has stated in his annual report, just rendered to the State Live Stock Sanitary Board, that during the past year one thousand cattle in this State were condemned as tuberculous and killed, their value being appraised at over twenty-five thousand dollars. Dr. Pearson also reports an outbreak of anthrax in Jefferson County, and several cases of rabies in different parts of the State. The excellent work of Dr. Pearson will be carried on this year unhampered by deficient appropriations, as it has been arranged that a sum of $40,000 shall be set aside for the expenses of the board during the fiscal year.

The 133d annual meeting of the Medical Society of New Jersey was held at Allenhurst, June 27th, 28th and 29th, the president of the society, Dr. Fisher, presiding. More than 150 delegates from the different county societies were present, and the meeting was very successful, both as to the scientific matter discussed and the business transacted. The society elected officers for the ensuing year as follows: President, Dr. L. M. Halsey; vice-presidents, Drs. Wm. Pierson, John D. McGill, and E. L. B. Godfrey; secretary, Dr. E. W. Hedges; corresponding secretary, Dr. Wm. J. Chandler, and treasurer, Dr. Archibald Mercer. The next meeting will be held at Atlantic City in June, 1900.

That smallpox prevails to a wide extent in Pennsylvania is shown by the last report of Dr. Benjamin Lee, secretary of the State Board of Health. This report, dated June 27th, states that no less than 146 cases of this disease have been reported since June 3d. Of this number forty cases occurred in Philadelphia. The majority occurred in the western counties.

OUR LONDON LETTER.

[From Our Special Correspondent.]

NO DECISION YET IN THE HUNTER CASE—THE ENGLISH CANCER SOCIETY AND ITS VIEWS ON PREVENTION—THE HARLEIN GOLD MEDAL TO LORD LISTER—HAFFKINE'S ADDRESS ON INOCULATION IN THE PLAGUE—LAWSON TAIT—SANITARY CONDITION OF LONDON—THE PROGRESSIVE LIVERPOOL SCHOOL OF TROPICAL MEDICINE.

London, June 24, 1899.

The General Medical Council has not yet reported its decision in the Hunter case, to which I have already referred, though that redoubtable warrior Victor Horsley is pushing the battle to the very gates. Its committee, of which Dr. Glover is chairman, reported in favor of the organization of a Conciliatory Board, which should mediate between the profession and the friendly societies and clubs in the serious clashes which are continually occurring. The council mildly approved of the theory of the report, but immediately thereafter emphatically refused to take any share in the formation of such a body, so "conciliation" seems as far away as ever. The council seems to continue in the same conservative frame of mind noted last week, as it flatly vetoed a proposition to increase the direct representation of the profession at large at its board by so much as a single member.

There is abundance of sporting enthusiasm in the English profession, and a fine healthy spirit it is. The "medical" dog-show, arranged by the Women's Medical School, proved a great success, attracting entries of nearly 250 dogs owned by members of the profession, and netting a handsome sum for the laboratory fund of the school. Week before last one of the leading golf clubs was the scene of a "medical tournament" which attracted much attention and many entries. And as every one whose early education has not been neglected knows, the champion cricketer of England, the uncrowned king of the athletic world, Dr. W. G. Grace, is one of us, not merely in name, but in fact. He has a large practice to which he devotes himself in the winter, turning it over to a partner for the summer, when the cricket season begins. And so far from injuring his practice, his fame as a batsman is said to be a decided advantage to him professionally, and his patients are immensely proud of his prowess. Oddly enough, by the way, the honors in the golf tournament were won by a "Dr. Jekyll," though whether "Mr. Hyde" appeared in the competition is not stated.

And after consumption, cancer. The English Cancer Society has just held its inaugural meeting, at which the usual melodramatic statistics showing an enormous increase were quoted and all true Britons urged to rally for its prevention. As even the pathologists among us are still completely in the dark as to the cause of cancer, just what form measures of prevention are to take, is distinctly hazy, but the society rises superior to such halting considerations. It demands elementary instruction in the schools in the laws of the prevention of cancer, and a Parliamentary Inquiry! This is the way to talk! Just let the disease understand that you're not going to stand any more nonsense, but are about to proceed to prohibit it by law, and threaten it with Parliamentary Inquiry, and like Davy Crockett's coon, it will "come down" at once. Prevention without knowing the cause is delicious! It reminds one how the "Hunters of the Snark," according to Lewis Carroll, "threatened its life with a railroad share."

At the anniversary dinner of the Royal Institute of Public Health the Harlein gold medal was presented to Lord Lister, in recognition of his invaluable services not merely to surgery, but to State medicine and sanitary science. We regret to learn that Lord Lister is at present somewhat severely indisposed, but it is hoped the attack will prove of but short duration. No honors can be too great or too many for him while he is still with us.

Professor Haffkine's address on "Inoculation in the Plague," before the Royal Society week before last was both interesting in itself and a high tribute to the importance and value of medicine in the eyes of its sister sciences. Agreement was almost unanimous among the experts present after the address that Haffkine's result compelled belief in the value and promise of his method. As many as 80,000 patients were inoculated in one place

(Hubli) and the sick and death rates were enormously lowered among them as compared with the uninoculated. The method of attenuation is by cultivating the plague bacilli in the presence of weak solutions of carbolic acid or oil of mustard, only the toxins of the attenuated bacilli being used in inoculation.

The inoculation has proved remarkably safe and innocuous, although its sensory effects were described by an immunized gentleman present at the session as "like fifteen vaccinations at once," and the natives are beginning to feel confidence in it, a most important tribute from the novelty-hating and cowardly Asiatic.

In this connection it will be of some little personal interest to American surgeons to learn that the antiseptic, flour of mustard, used with such excellent results by many of them in their operation-preparations, on the recommendation of Roswell Park, has been found by Haffkine one of the most efficient germicides against even the virulent plague-bacilli.

Bacteriology has just scored another triumph in the service of man; this time not by directly preventing or curing his diseases, but by what really amounts to the same thing—protecting his food-supply. Dr. Edington, Bacteriologist to Cape Colony, South Africa, whose interesting results in Texas fever were noted in a recent letter, announces the discovery of a parasitic fungus highly fatal to locusts and with which he has succeeded in almost clearing several farms and gardens of these pests.

As you already know, Lawson Tait died suddenly at his home, on the Welsh coast, on June 13th in the fifty-fifth year of his age. No recital of his triumphs and his services to surgery is needed, for his name has been a household word in the entire English-speaking medical world for twenty years past. In spite of many eccentricities and even "defects of his virtues," Lawson Tait was a genius, a reformer of the fighting type, and sincerely devoted to the interests of the profession—as he understood them. His work in abdominal surgery will remain a permanent monument to his memory of which any man might be proud. The surprising thing is that he could have written his name so high at such an early age and in spite of what the French aptly term his "difficult" temperament. An Ishmaelite of the Ishmaelites, he fought and flouted both antisepsis and vivisection, and yet his superb results by purely aseptic methods did much to turn the current of professional thought in the direction of this higher step. His curt reply to the German surgeon before the days of antisepsis who visited him, and asked the secret of his success, "I keep my finger-nails clean, sir!" accompanied as it was by a glance at the "mourning"-tipped fingers of his visitor, will live as the aseptic theory in a nut-shell.

The Anglo-American *entente cordiale* continues to flourish. Last week's *British Medical Journal* devoted an editorial to a notice and cordial commendation of the report of our Minnesota State Board of Health, and expressed its regret that the multiplicity of health authorities in London prevents its sanitary system from even approaching the scientific uniformity and efficiency of the Minnesota plan.

The sanitary situation in London is really becoming a serious one. From time immemorial the world-capital has been divided, upon the most irrational of principles, into "parishes" based upon the area of influence of the great churches, each ruled by its "vestry," whose intelligence and progressiveness may be imagined, each of which was absolutely independent and practically responsible to no higher power. Some thirty years ago these bodies made a sort of working-compromise, of the makeshift order, by appointing a Metropolitan Board of Works in whose care the streets, parks, and a few other universal interests were placed. About ten years ago this was further improved upon by the new London County Council, which has done yeoman service for sanitary reform, but now Mr. Balfour's precious new London Local Government Bill proposes to relegate sanitary matters again to a lot of newly created "boroughs," so that the County Council has formally refused to take even badly needed sanitary steps, such as the appointment of additional meat-inspectors, etc., on the ground that it does not feel justified in making any large expenditures on schemes which will be entirely upset in less than two years when the new boroughs come into power.

Major Donald Ross began his lectures on the "Extirpation of Malaria" at the Liverpool School of Tropical Medicine last week, and an investigation expedition is to start from this progressive little school no later than August for Sierra Leone on the west coast of Africa. Score another point for the superiority of private over government enterprise! Indeed the word seems a mockery in its last connection. The London Government School still "expects" to be open in October, although half the staff of its hospital has resigned on account of discourteous and dishonorable treatment.

The Commission of Experts appointed by the government has completely disposed of the silly charges against the milk from the Aldershot sewage farm which, as we intimated in a former letter, rose solely out of the jealousy of competing local dairymen.

TRANSACTIONS OF FOREIGN SOCIETIES.

COLOTOMY FOR MEMBRANOUS COLITIS—TREATMENT OF ABSCESS IN THE ANTRUM—HEMORRHAGIC ERYTHEMA IN A CASE OF BRIGHT'S DISEASE—REMOVAL OF SUBCLAVIAN ANEURISM—TREATMENT OF GONORRHEAL SALPINGITIS — DECLINE OF TYPHOID FEVER IN THE NETHERLANDS.

AT the Clinical Society of London, May 12th, WHITE and GOLDING BIRD contributed a paper on right colotomy for chronic colitis, the object of the operation being to give the colon perfect rest. Three cases were mentioned, the first that of a lady, aged thirty-six years, who had had membranous colitis for twenty years. She was wasted, a complete invalid, and almost unable to take food, or any exercise. Right lumbar colotomy was performed in two stages, with a six-day interval, and the fistula allowed to remain open for a year. Six months after its closure the patient was perfectly well, eating ordinary food, and taking out-of-door exercise. Two other

more recent cases were reported, in which right lumbar colotomy was performed with excellent result. The fistulæ were still open. Right-sided colotomy was therefore recommended for: (1) intractable membranous colitis; (2) all forms of chronic ulceration of the colon that had resisted medical treatment, and which were obviously otherwise incurable. Most cases of very chronic dysentery were probably to be cured without colotomy. (3) Cases of idiopathic dilatation of the colon. The colotomy must be right-sided, and colotomy is preferable to cecotomy, for when the latter operation was done fluid feces escaped from the artificial anus, and this gave rise to much trouble; while, further, it was difficult to prevent some feces passing on into the colon. More experience is needed to determine the length of time which the bowel should be left open, but certainly six months should be the minimum.

THOMSON mentioned a case of empyema of the maxillary sinus which had existed for two and possibly for seven years, and which had been completely cured in eight weeks by drainage through a tooth-socket. A drill was used to open the sinus, and a drain was employed. The only other treatment was a daily washing with an alkaline antiseptic solution. This simple method of treatment, first employed by Cowper more than 200 years ago, has lately been described as futile in long-standing cases.

OVELL and EVE said that the simpler operation should be tried first; but that in a minority of the cases it was unsuccessful on account of the polypoid growths in the antrum. In such cases treatment consisted in freely opening the antrum through the canine fossa so that the cavity could be inspected and the growths removed; and in two instances a counter opening was made through the inner wall of the antrum at the level of the floor of the inferior meatus. The cavity was first packed with iodoform gauze, and afterward treated with antiseptic irrigation. All of the patients that had been so treated by them had been cured except one, and he had been greatly benefited. They also reported a case of malignant disease of the antrum, in which suppuration was the only symptom noted, and in which the presence of a tumor in the antrum was not suspected until the opening had been made through the bone. Subsequently the superior maxilla was successfully removed.

May 26th, FOX related an instance of hemorrhagic erythema in a case of Bright's disease. The patient, a woman, aged sixty-one years, suffered from an acute trouble supervening upon a long-standing affection of the kidneys. The hemorrhagic symptoms referred to were: injected and swollen fauces, some erythematous maculæ on the face and a few petechiæ on the legs. Five days later a generalized eruption of a macular type made its appearance. The macules were slightly raised, with a tendency toward rapid centrifugal extension. Their size varied from that of a pin-point to a diameter of half an inch or more. They soon became confluent. The color was a vivid red, not affected by pressure. The older lesions had purple borders and bluish-red centers. The hands and feet of the patent were edematous, and the affection looked like a severe purpura. Later the lips were swollen and blood stained, and there were a few spots on the gums. The lesions became increasingly hemorrhagic and the patient died seven days after the general eruption began. The trachea, bronchi, stomach, and colon were intensely injected, and in the small intestine there were, besides, numerous hemorrhagic areas. The kidneys were small and granular. No micro-organisms were discovered. The eruption was thought to correspond clinically with the roseola of Willan, rather than with erythema multiforme. The speaker's experience with eruptions in nephritis led him to look upon them as heralds of approaching death. They were either of the type of Willan or morbilliform in character.

ALLINGHAM reported a case of aneurism of the right subclavian artery. The vessel was ligated in its first portion, and thirty-eight days afterward the aneurism was successfully removed. The patient recovered good use of the arm, although two-thirds of the clavicle had been taken away. It was interesting to observe that pulsation returned in the radial artery within twelve days of the time of ligature. Hence the importance of removal of the sac in these cases.

DUCKWORTH said that he was treating a similar case in which he had considered operation, but postponed it in order to try the effects of rest, restricted diet, and iodid of potash. The aneurism was consolidating and shrinking, so that it seemed still unnecessary to perform an operation.

SYMONDS mentioned a case in which he had attempted to ligate the first portion without removing the clavicle. On passing the needle under the vessel alarming hemorrhage was produced. When the needle was withdrawn the bleeding ceased. He therefore tied the innominate and common carotid simultaneously. So far the patient had done well.

At the British Gynecological Society, May 11th, TAYLOR read a paper on the treatment of gonorrheal salpingitis. A large number of women who are suffering from tubal disease have been at some time or another exposed to the infection of syphilis as well as of gonorrhea; and they undoubtedly show marked improvement after a prolonged course of mercury and iodids, and in the course of this treatment, unless acute pyosalpinx intervenes it is the rule for all gross physical signs of disease to slowly and permanently disappear. Acute pyosalpinx is peculiarly liable to occur on the left side of the body, probably as a result of secondary infection from the rectum. Such cases, whenever possible, should be treated by free incision of the posterior vaginal fornix, by thorough exploration and emptying of all pus-cavities from the pouch of Douglas, and by iodoform-gauze drainage. The older operation of removal of the appendages is not only much more dangerous, but is peculiarly liable to be followed by fecal fistula and operation-sequel sometimes worse than death itself. If the recovery is not complete, relapses following the operation should be followed by a course of specific treatment, the beneficial result of this being often immediately manifest when the wound tissues are unhealthy and the healing is delayed. Occlusion of the tubes and peritubal adhesions consequent on gonorrheal

salpingitis have no direct specific causation, and must be regarded rather as secondary mechanical results of the local peritonitis, which has been caused by salpingitis. Their absorption and disappearance will not therefore be secured by the cure of the gonorrhea, and sterility may persist, although gonorrhea may be entirely eradicated from the system. In gonorrhea of the pelvis there will probably remain a residuum of intractable cases, particularly cases of complication with other diseases, such as fibroids of the uterus. In these cases, vaginal hysterectomy, with or without removal of the appendages, is not only the most rational operation in theory, but is productive of the best final results.

At a meeting of the Epidemiological Society, held May 19th, SALTET read a paper on typhoid fever in the Netherlands. He showed that while the general death-rate per 100,000 from all diseases had declined by 14 per cent. since 1872, and that for tuberculous disease by 16 per cent., that for typhoid fever had declined by 63 per cent. The mortality in the towns from typhoid fell 72 per cent., while in the rural districts it had fallen only 60 per cent. The improvements in sanitation seemed to him insufficient to account for this great decline in the mortality in typhoid, while the decline in other diseases was far less. He suggested that the progress of medial science had far more to do with it than was generally admitted. This theory would explain the greater decrease in the urban centers, than in the rural districts, although the latter would naturally be freer from communication of infection, by the better medical facilities offered the inhabitants of the cities.

NOTTER remarked that the stationary character of the population of the Netherlands would favor their acquisition of a degree of immunity. In India the extreme susceptibility of recently arrived Europeans is notorious while with each year of service there is a rapid increase in their power of resistance.

SOCIETY PROCEEDINGS.

THE AMERICAN SURGICAL ASSOCIATION.

Abstract of the Proceedings of the Twentieth Annual Meeting, Held at Chicago, May 31, June 1 and 2, 1899.

THE Association met in the Hall of the Chicago Medical Society, and was called to order by DR. W. W. KEEN of Philadelphia. PROFESSOR DE LASKIE MILLER of Chicago delivered an Address of Welcome, which was responded to by the President. Dr. KEEN then delivered his address. He selected for his subject "The Technic of Laryngectomy."

He began by saying that he has been ill satisfied with the usual technic of laryngectomy, and, as in a recent case, he adopted a method which rendered the operation one of simplicity, caused but little loss of blood and little shock, and avoided the danger of aspiration pneumonia, he ventured to bring it before the Association in the hope that it will be tested by others so as to determine its real value. Instead of being a very severe and dangerous operation, as it has hitherto been regarded, he hoped this will place it in the category of safe operations.

Nearly all authors, whether surgeons or laryngologists, speak of the operation as an extremely severe and dangerous one, and this view is warranted by its past high mortality. The causes of the mortality are chiefly: (*a*) Weakness of the patient by reason of the disease, the poor aeration of the blood, and the entrance of septic discharges from the diseased larynx into the lung before the operation; (*b*) shock, including hemorrhage during the operation, and (*c*) after the operation, septic pneumonia, due to the aspiration of infected wound-fluids. This is the greatest danger of all. The sources of these wound-fluids are twofold: first, the tracheotomy wound, if, as is usual, tracheotomy has been done; and, secondly, the wound left by the removal of the larynx. These wound-fluids are usually infected from the food, the secretions of the mouth, and the packing by iodoform gauze which renders primary union impossible.

While the method which he was about to describe does not obviate the weakness or any other unfavorable influence from the general condition of the patient prior to operation, it minimizes the other causes of death, and especially the possibility of pneumonia.

He could not claim originality for any one of the steps, for they have all been employed, he believed, by others. Thus Bardenhauer closed the communication between the trachea and the pharynx, but he only kept it closed until the wound became covered with granulations, and complications were no longer to be feared, say fourteen days. The communication was then reopened for the insertion of an artificial larynx. After adopting this method he had had four recoveries, while by the former method he had had four deaths. Cohen united the stump of the trachea to the skin, one of the most important improvements in the technic, since it prevents in a large measure the access of wound-fluids to the lungs. Other surgeons also have used the Trendelenburg posture, etc. But as a systematically planned operation, combining many advantages, the present technic as a *tout ensemble* may be called original.

1. The general preparation of the patient is the same as for any other operation.

2 *Preliminary Disinfection.*—As in all cases about the mouth, nose, pharynx, and larynx a systematic attempt is made for two or three days beforehand to secure at least partial disinfection. While partial disinfection is not as good as complete, yet the results in treatment of fractures of the base of the skull, in the extirpation of rectal tumors, etc., shows its great value. The teeth are very carefully cleansed by the toothbrush. If there are any old stumps of teeth present it is better that they should be extracted, and the operation deferred a few days until these dental wounds heal. For two or three days before operation every two hours, when the patient is awake, the mouth and each nostril is sprayed separately with a solution of boric acid, listerin, or both.

3. *Tracheotomy.*—Nearly all authors recommend a tracheotomy, either as the first step of the operation or more frequently ten to fourteen days before operation.

In the few cases in which dyspnea is great the author would be disposed to do a tracheotomy, say two weeks before the laryngectomy; not, however, with a view of preventing the entrance of blood and wound-fluids into the lungs by the introduction of a tampon cannula, but for the purpose of improving the general condition of the patient.

4. *Posture.*—The entire operation, after the trachea is invaded, is performed with the patient in the Trendelenburg position. The speaker was persuaded that the majority of surgeons do not appreciate to its full the advantages which this posture possesses in all operations about the upper air passages. As he had pointed out in a previous paper, he employs it in epithelioma of the lip, in extirpation, or other operations on the upper and lower jaw, in removal of the tongue, in cleft palate, in operations on the tonsils and pharynx, and all similar operations. Blood will not run up hill any more than water, hence, if the surgeon employs this posture in laryngectomy he avoids one of the chief reasons for tracheotomy and the employment of a tampon cannula.

The disadvantages of tampon cannulæ are very great. Kocher, like himself, has lately dispensed with them entirely. The three most commonly used are those of Trendelenburg, Hahn, and Gerster. Of the three Gerster's is distinctly, in his opinion, the best. It can be more accurately adapted to larynges of varying sizes, and is much less likely to injure the parts either by undue pressure or by difficulty of introduction.

5. *Anesthesia.*—This is carried out at first through the mouth, and is continued until the larynx or trachea is invaded. A large tracheotomy cannula (12 millimeters in diameter) is then introduced and held in place by disinfected tapes tied around the neck. The inner tube of this cannula is removed and the metal tube of a Hahn cannula, which precisely fits it, introduced. A rubber tube connects this with the ordinary funnel for the administration of chloroform.

The essayist described the operation in detail, and then spoke at length regarding the after-treatment. The patient is kept in the Trendelenburg position by placing a chair under the foot of the bed. This posture prevents any wound-fluids from running down (or rather up) into the lung. This position is to be maintained for one day. On the second day the bed is lowered to the horizontal plane. On the third day the patient is allowed to sit up in bed on a bed-rest; on the fourth, to get out of bed and sit in a reclining chair, and on the fifth day he may walk about the room.

For two days nutritive enemata only are to be used. After that a teaspoonful of liquid food is given, at first every half hour, always followed by a tablespoonful of sterile water to wash away any food that might possibly leak into the laryngeal wound. At the end of a week full diet as to quantity may be given, but no solid food is to be given until the tenth day. No catheter or esophageal tube is required. On the day after the operation the small gauze drain is to be removed. Half of the stitches may be taken out on the fourth day, and the remainder on the sixth day.

The only objection to this method which occurred to the author is that it absolutely precludes the use of any artificial larynx. But the possession of voice is nothing when compared with a speedy recovery and a greatly diminished danger of a fatal result. Rutsch believes such a larynx is very unsatisfactory.

At the conclusion of the president's address a symposium on "The Surgery of the Spanish War" was taken up. The first paper was read by DR. NICHOLAS SENN of Chicago, and was entitled, "The First-aid Package in Military Surgery." He stated that two things were brought out clearly during the Græco-Turkish War, namely, the value of a first-aid antiseptic occlusive dressing in the prevention of wound infection, and the importance of immediate immobilization of compound gunshot fractures. He suggested the following first-aid package for field use and emergency work: Two pieces of lintin, a form of compressed cotton, four inches wide and sixteen inches long, sterilized and folded twice lengthwise; a teaspoonful of borosalicylic powder in a small waxed aseptic envelope; between them a piece of sterile gauze, forty-four inches square, with two safety pins, folded to corresponding size with the lintin compress; all of these articles wrapped in tin foil; two strips of rubber adhesive plaster an inch wide and eight inches long, the whole to be sewed in an impermeable canvas or linen cover. In using the package the powder is applied to the wound, the linten used as a compress being held in place by the strips of adhesive plaster, and the gauze bandage placed over it. If two wounds are to be dressed at the same time, as is usually the case in modern warfare, the contents of the package are equally divided and used, which can be done without materially impairing the efficiency of the dressing. The slight hemorrhage in wounds inflicted by the small-caliber bullet will soon saturate a part of the dressing, which by evaporation will soon convert the antiseptic powder and the cotton into a dry antiseptic crust, the very best protection for the wound against infection. Many military surgeons have expressed themselves recently as being opposed to the employment of the first-aid package by any one except medical men. This position the speaker thought will be found untenable during any great war, when the number of wounded would greatly exceed the working capacity of the limited number of surgeons. In summarizing the following conclusions were emphasized:

1. First-aid packages are indispensable on the battlefield in modern warfare.

2. The first-aid dressing must be sufficiently compact and light to be carried in the skirt of the uniform or on the inner surface of the cartridge or sword belt, so as to be of no inconvenience to the soldier or in conflict with military regulations.

3. The Esmarch triangular bandage is of great value in the school of instruction, but in the first-aid package it is inferior to the gauze bandage.

4. The first-aid dressing must be applied as soon as possible after the receipt of the injury, a part of the field service which can be safely entrusted to competent hospital-corps men.

5. The first-aid dressing, if employed behind the firing-line, should be applied without removal of the clothing over the injured part, and fastened to the surface of the skin with strips of rubber adhesive plaster, the bandage being applied over and not under the clothing.

6. The first-aid dressing must be dry, and should remain so by dispensing with an impermeable cover over it, so as not to interfere with free evaporation of the wound secretion.

7. The first-aid dressing should not be disturbed unnecessarily, but any defects should be corrected at the first dressing-station.

A paper, entitled "The Battle-ship in War," was read by DR. N. M. FEREBEE, Medical Inspector of the United States Navy, Norfolk, Va. He described a modern battle-ship, spoke of the preparations for, and the conditions during, war. He also narrated his experiences with modern rifle-bullets and with shells, and closed his paper by detailing interesting cases.

"The Organization and Equipment of Military Field Hospitals" was the title of a paper read by DR. GEORGE R. FOWLER of Brooklyn. Under the head of organization the essayist dealt with executive offices, dispensary, property office, post-office, quartermaster's office, commissary office, medical ward, surgical ward, operating-tent or pavilion, pathological and bacteriological departments, cooking department, diet-kitchens, sanitary and disinfection departments. In referring to location and arrangement, he spoke of the importance of selecting a suitable site, and then dwelt upon soil, drainage, arrangement of the wards, sinks, and emphasized the importance of cremating garbage and typhoid excreta.

In referring to equipment, he spoke of tentage, pavilions, furniture, linen, medical supplies, anesthetics, antiseptics, instruments, sterilizers, operating-tent furniture, ligature and suture materials, dressing materials, splint materials, and transportation facilities. Lastly, he dwelt at length upon the personnel, which comprises executive and administrative officers, professional staff, ward officers, operating-staff, ophthalmologist, aurist, and dentist.

DR. CHARLES B. NANCREDE of Ann Arbor, Mich., followed with a paper on "The Effects of Modern Small-arm Projectiles as Shown by the Wounded of the Fifth Corps." Reports show that about 1400 wounded were cared for at the hospital with which he was connected, for nearly all of the injured in this corps who survived for twenty-four hours sooner or later passed through their hands, so that flesh wounds, and those of a day to a week or more, were observed. Flesh wounds were always of a trivial nature, unless the ball became deformed by striking some extraneous object or when stripping its mantle, as it sometimes did. This immunity enjoyed by the flesh wounds caused by Mauser and Krag balls resulted, first, from the slight amount of contusion caused by the rapidly moving ball; second, the aseptic condition of the ball, and, third, the rarity of the carriage of fragments of clothing into the wound, as was not uncommonly done by the forty-three-caliber Remington, brass-mantled balls. If maintained aseptic, the majority of flesh wounds healed almost as if they had been incised wounds, not uncommonly cicatrizing under the primary field dressing made with the first-aid package.

Contusions, or slight wounds of the great vessels leading to so-called traumatic aneurisms, or aseptic or septic sloughing of the vessels many days after the receipt of the wound, were far from uncommon. Thus, he saw one wounded subclavian where the patient survived over three weeks, to finally succumb to hemorrhage during an attempt to ligate the vessel, which was torn for a long distance. He also knew of another dying on the table some weeks after being wounded during an attempt to secure the same vessel. He tied the common femoral for wounds and assisted a colleague in securing another, days after the receipt of the injury. He tied one radial for secondary hemorrhage, and ordered the tying of an ulnar for ball injury several days after their division, and was compelled to amputate an arm after failing to secure a bleeding brachial in an apparently aseptic wound two weeks after the man had been shot.

The greatest advance in military surgery on the battle-field in recent times is the first-aid packet, and the greatest boon conferred on the wounded soldier has been asepsis and antisepsis, because in the majority of instances rendering his injuries so painless and their complications so slight that even anesthetics no longer occupy the chief place as a blessing to the wounded, because comparatively rarely needed.

DR. M. H. RICHARDSON of Boston read a paper on "Appendicitis; Should Every Patient Be Operated upon as Soon as the Diagnosis of Appendicitis Is Made? Should the Appendix Be Removed in Every Case?" At the bedside, in a specific case of appendicitis, there would be doubtless little difference of opinion among even those surgeons who seem to differ materially in the expression of their views. What one may describe as a severe case another may regard as a mild one; what one may consider a hopeless infection, another only a desperate one, and so on. The conclusions arrived at are the result of experience in 904 cases, personally observed and treated, and of personal observation of many others in the practice of hospital colleagues. In 259 cases of operation in acute cases 72 patients died. Four of these deaths were in the hands of other surgeons. In 189 acute cases operation was not performed: of these, 31 patients died.

Many of these fatal cases were desperate ones. All were severe. The mortality in acute cases without operation was fully 31 in 189 cases. In practically all of these fatal cases the patient was moribund and the case hopeless when first seen.

The most important question is not whether to operate in appendicitis, but rather when to operate. In view of the great mortality after operation in severe cases; of the disadvantages following the drainage necessary in septic cases, weakness of muscles, stretching of scars, hernias, and the like, the best time to operate is during the period of perfect health following the attack. In a large percentage of acute cases recovery from the acute attack will take place, and operation can be safely performed through a small incision which will not weaken the abdominal

wall. After the initial stage the question of intervention becomes more difficult when observed for the first time on the second, third, or fourth days. In severe cases the patient should be operated upon at once, unless he is improving so rapidly that there is a strong expectation of complete recovery. Intervention is still more strongly indicated if the symptoms are increasing in severity. Operation is indicated, too if the symptoms after marked improvement recur. In the consideration of symptoms after the early hours, the character and extent of pain, tenderness and rigidity are important as determining the width and depth of the area of infection. The constitutional signs are less reliable than the local; they may be deceptive guides.

The chief objection to operating in every case is the danger of converting a localized into a general infection. If the patient is improving, with a successfully localized peritonitis of considerable extent, especially if centrally localized, as in the pelvis, operation should be postponed until intervention can be safely practised, because these cases, in the absence of general peritonitis, are the most dangerous ones. An attempt should always be made to remove the appendix whenever the peritoneal cavity is opened unless the patient's condition forbids prolonged search. In many cases of abscess with firm walls a slough will be found which on examination will prove to be a necrosed or exfoliated appendix. In such cases no subsequent operation for removal of the appendix will be necessary. If, after recovery from simple drainage in acute appendicitis, there is evidence of renewed appendicular trouble, the appendix should be removed, the scar of the original wound incised, and the wound carefully closed. The operation is especially desirable if there is hernia in the scar or even stretching or discomfort. Hernia of itself after all operations for acute appendicitis should be operated upon if it causes discomfort or disability. In very rare instances there may be a recurrence of infection in the region of the ileocecal valve, even after removal of the appendix.

The discussion on Dr. Richardson's paper was opened by DR. JOHN B. DEAVER of Philadelphia who said that the paper had brought out many points on appendicitis about which an active warfare had been waged for some years. Upon the surgeon's individual decision at the bedside often depends the life of the patient, and in every case the very points about which the paper dealt have to be faced and a decision made. As to the question: Should every patient be operated upon as soon as the diagnosis is made? his answer was yes, with two exceptions: first, in cases of acute active general peritonitis; second, in collapse. Should the appendix be removed in every case of appendicitis? Yes, with the exception of those cases in which the bowel forming a part of the abscess wall has undergone necrotic changes rendering the bowel friable and apt to rupture during the necessary manipulation.

Dr. Richardson had most wisely divided his first heading into two classes: those in which the diagnosis has been made in the early hours (and the speaker took it for granted that he meant within twenty-four hours), and those in which a diagnosis is made after this period of time had elapsed. In answer to the first question, Dr. Deaver asserted most emphatically that the early hours is the time *par excellence* for operation in this most serious of intra-abdominal affections, first, because practically all patients operated upon at this time get well, or at least give the lowest mortality, this mortality increasing with the interval between the onset of the attack and the time of operation. Thus, of 18 patients operated upon within the first twenty-four hours, only 1 died, a mortality of 5.5 per cent. In 30 acute cases, on the other hand, in which the patients were operated upon within forty-eight hours, 10 died, a mortality of 33 3 per cent. As far as his experience goes, a careful examination of the statistics of acute cases convinces him that the local pathological changes reach by progressive stages their severest limit within the first forty-eight hours, and after that period the changes are more in the nature of sequelæ following the primary stage of infection. Second, the percentage of individuals that have one attack and then remain perfectly well and free from other attacks is very small. Of 460 in his own experience 312 had more than one attack.

Should one operate when the diagnosis is made after the early hours, if the symptoms are severe? His experience has led him to the belief that symptoms are very unreliable and are not in proportion to, nor do they indicate the severity of, the pathological processes which are taking place in the belly. Many times he has opened the belly of a patient with a normal temperature, flat belly walls, and a quiet retentive stomach, in whom tenderness on deep pressure was the only sign of persistent trouble, and has found pus or a gangrenous and perforated appendix. The surgeon who waits in the case of appendicitis for the appearance of severe symptoms, or, worse yet, waits for an indication to operate until the symptoms increase in severity will have many unnecessary deaths to his credit.

Should the appendix be removed in the case of localized abscess with firm walls? Success, under these circumstances depends upon the skill and the technic of the surgeon. The appendix should be removed, the only occasion for difference of opinion being as to the time of its removal, *i.e.*, at the primary operation or at a subsequent operation. If the appendix can be removed at the primary operation without additional risk to the patient, it seemed to the speaker that this is the time of election. That it can be done without additional risk has been repeatedly demonstrated, and in his own practice he does it in nearly all cases, because in 257 primary removals his death-rate in the past has been 16 7 per cent., and in 13 secondary removals the death-rate was 30.7 per cent. The reasons for the removal under these conditions are that surgeons do not subject their patients to the danger of an attack of acute appendicitis occurring before the secondary operation. There is less likelihood of fistulæ, either fecal or simple. The patient is cured with one operation instead of two, with the consequent saving of a variable period of invalidism. The appendix can hold but one of a few positions. It must be either post-cecal, pointing into the pelvis toward the spleen, or confined in the ileocolic, or subcecal, or ileocecal fossa. If it is embedded in exudate,

the exudate itself will indicate its position. He agreed with the essayist as to the necessity of the ultimate removal of the appendix, differing from him only as to the length of time before the complete operation is performed.

DR. CHRISTIAN FENGER of Chicago endorsed in the main nearly everything that Dr. Richardson had said. He, however, disagreed almost entirely with the views expressed by Dr. Deaver.

DR. FRANCIS B. HARRINGTON of Boston thought there was very little difference of opinion between Dr. Richardson and Dr. Deaver. He said that Dr. Deaver did not operate in every case; he considers the condition of the patient. If the patient is in collapse, he waits, and so do all surgeons. It is better to wait not only in cases of collapse, but in other instances. He likes to remove the appendix in every case in which it is possible to do so. On the other hand, there are certain conditions in which he is inclined to wait perhaps twelve or twenty-four hours, or even longer, before operating.

DR. JOSEPH RANSOHOFF of Cincinnati thought the doctrine advocated by Dr. Deaver would do a great deal of harm if followed by most men who operate upon patients with appendicitis. An important point to remember is that five-sixths of the operations for appendicitis are performed by general practitioners, men who have had very little experience in handling the intestines, in dealing with abscesses within the cavity of the abdomen, etc.

DR. NICHOLAS SENN of Chicago said that uniformity of practice in the treatment of appendicitis would probably never prevail. Each man formulates his own indications and follows his own rule of practice. Personally he felt weakest in making an early diagnosis in the first attack.

"Nephrectomy *versus* Nephrotomy" was the title of a paper by DR. JOSEPH RANSOHOFF of Cincinnati, Ohio. He said that renal surgery is essentially the product of the past twenty years. The occasional operations on the kidney performed before that time paved the way for a clearer appreciation of the conditions demanding operative relief. Improvements in the method of examination, and the consequently greater accuracy in diagnosis, the recognition of the early gross changes wrought by disease, as seen by operation rather than by autopsy, and the comparative safety of incisions through healthy kidney tissue have brought to the fore the element of safe conservatism in the domain of renal surgery. Several interesting and instructive cases of pyonephrosis were reported. Nephrotomy, *per se*, is doubtless an operation nearly devoid of danger. When performed on a healthy kidney, as for stone, the mortality is less than 5 per cent. When performed for suppurative diseases, the mortality rises. He had tabulated records of 78 nephrotomies for pyonephrosis exclusive of tuberculosis published within the last three years from various clinics. Of these 78 nephrotomies, 17 were followed by death, a mortality of 21.8 per cent. In the hands of some surgeons the mortality has been very large. Four out of 5 cases were fatal in the Vienna clinic. Out of 6 cases of nephrotomy at the Roosevelt Hospital 3 patients died. On the other hand, Israel lost only 1 patient out of 8, and Thornton 1 out of 12. From the same sources he had tabulated 37 primary nephrectomies with 9 deaths, giving a mortality of 24.3 per cent., and 17 secondary nephrectomies, with 7 recoveries and 10 deaths, a mortality of 58.8 per cent. The advantages of nephrotomy for pyonephrosis are obvious: First, it is an operation readily tolerated even in patients greatly reduced by fever. Second, it permits the surgeon to determine the condition of the opposite kidney Third, by it the saving of even a small amount of functionating kidney tissue may throw the balance in favor of recovery. In dealing surgically with a pyonephrotic kidney, statistics can guide the operator only in a general way in the choice between nephrectomy and nephrotomy. Nephrotomy is indicated in pyonephrosis, first, when the condition of the opposite kidney cannot be ascertained; second, when the reduced condition of the patient will not permit the major operation if this is indicated The nephrotomy is then but the preliminary step, to be followed by nephrectomy as speedily as possible. Third, when the operation reveals the presence of considerable kidney tissue, and an approach to the normal on the part of the pelvis and proximal portion of the ureter. Here a ureteroplasty may avert the need of nephrectomy. Fourth, when there is evidence or suspicion of disease in the other kidney.

Primary nephrectomy is indicated, first, when there is a sound second kidney. Second, when inspection of the exposed kidney shows many or large pouches that cannot be successfully drained. Third, when there is a little kidney tissue left. Fourth, when an examination of the pelvis and proximal portion of the ureter makes it reasonably certain that a return to the normal cannot take place. Fifth, in para- and perinephric suppurations where the kidney acts as a valve, impeding successful drainage. (Israel.)

DR. FRANCIS B. HARRINGTON of Boston then read a paper, entitled "Hernia Following Operations for Appendicitis." He had made a personal examination of the condition of the abdominal wall in 236 cases of appendicitis in which operation had been performed at the Massachusetts General Hospital by various surgeons. The subjects represented all varieties of the disease. The period which had elapsed since operation varied from nine months to nine years. No case was included in which operation had been performed since July, 1897. Total number examined, 236; males, 190; females, 46; 27 true hernias in all—11½ per cent.; 21 true hernias in males—11 per cent.; 6 true hernias in females—13⅓ per cent. Eighty-five wounds closed at the time of operation, 3 hernias, 3½ per cent.; 85 wounds partly closed at the time of operation, 11 hernias, 12½ per cent.; 63 wounds left entirely open at the time of operation, 13 hernias, 20 per cent. If with these cases of true hernia are included 10 cases of punctiform hernia and 53 cases of more or less bulging in the scar which did not constitute true hernia, the following percentage of weak scars is noted: in 85 closed wounds, 6 per cent.; in 88 partly closed wounds, 51 per cent., and in 63 open wounds, 62 per cent.

An opening between muscles or tendons or both could be detected in the scars: In 85 closed at the time of operation, 26 per cent.; in 88 partly closed at the time of operation, 83 per cent.; and in 63 open wounds, 87 per cent. There was general abdominal bulging in 85 closed incisions, or 7 per cent.; in 88 partly closed incisions, 45 per cent., and in 63 open incisions, 46 per cent. During the period in which these patients were operated upon, that is, from 1888 to 1897, some of the muscles or tendons were cut at right angles to their fibers in the acute cases, and often in the cases in which the wound was tightly closed at the time of operation. The writer advocated the use of an enlarged McBurney incision in all acute cases, which obviates the cutting transversely of any muscle or aponeurosis.

DR. ALBERT VANDER VEER of Albany, N. Y., followed with a paper on "Some Unusual Cases of Appendicitis with Complications." Operative surgery, in its relation to the appendix, will ever present rare and unusual cases. This was brought out strongly last year when the president of the Association and others detailed the histories of some very unusual lesions of the abdomen. Surgeons may examine their patients with ever so much skill, employing diagnostic intelligence to the best advantage, yet when they enter the peritoneal cavity they must be prepared for surprises. From the knowledge acquired from these isolated and rather rare cases it is more possible to increase the percentage of recoveries. A hernial sac with the appendix therein is not particularly rare, but to find it with a foreign substance like a pin, immediately in the appendix, and not having caused trouble, is somewhat unusual. To operate for the relief of femoral hernia and find not only the appendix, but a prolapsed bladder in the female, is certainly decidedly rare. The essayist then detailed eight somewhat unusual and complicated cases.

DR. DUDLEY P. ALLEN of Cleveland, Ohio, presented a paper, entitled "Cases of Fracture of the Skull Followed by Recovery." He reported ten cases of fracture of the skull, all but one of them involving the base. The first five reported were fractures at the base of the skull without any injury to the vault. Of these, three of the individuals were rendered totally unconscious at the time of the accident, one was in a semiconscious condition, and the third, so far as could be ascertained, retained consciousness. Bleeding from both ears occurred in two of these cases, whereas in three of the cases there was bleeding at only one ear. Deafness in one case occurred in both ears at the time of injury. Whether in the other cases deafness occurred at the time of injury could not be definitely determined. In two of these cases, however, deafness was complete and permanent in one ear, and in one case the hearing was much impaired in one ear. Loss of smell was complete in one case and greatly impaired in one case. Paralysis of one side of the face occurred in two cases, in one of which it remained permanent. These five patients with fracture confined to the base of the skull are alive and well at the present time, except for the disabilities just described.

There were two cases of children who fell from heights upon the vault of the skull, causing most extensive fracture and great deformity of the cranium. In one of these cases there was a great deal of hemorrhage from the ears. In both the scalp was lifted, the cranium was laid bare, and by means of a hook the fragments were raised to their normal positions. Both patients recovered. One, however, has impaired hearing in one ear.

Two patients received injuries in the frontal region extending into the base. In one of these there was extensive injury to the frontal bone and a large amount of bone and considerable lacerated brain tissue was removed. There was a fracture in this case extending across above the frontal eminence to the temporal fossa, upon the opposite side of the skull to that which received the greatest injury, and there was a fissure from the base of the skull extending from the frontal bone backward to the sella turcica. This patient had a large cerebral hernia. In the other case the injury to the frontal region and the involvement of bone was small.

The point of interest in the latter case was the temperature, which rose gradually at two different periods to 105° F., the case presenting many of the symptoms of typhoid fever with relapse. The other characteristic symptoms of typhoid fever were, however, entirely lacking, and the presence of optic neuritis, indicating probably a basal meningitis, placed the diagnosis of the cause of fever in considerable doubt.

The tenth case was one of severe injury in the region of the right parietal bone, followed in some weeks by impairment of mental activity, and also of motion of the right arm and leg. This was found to be due to a large subdural collection of blood on the left side, notwithstanding there was no evidence of injury on that side. The accumulated blood amounted to several ounces. It was removed and the patient is now well.

The following officers were elected for the ensuing year: President, Robert F. Weir of New York City; first vice-president, Charles B. Nancrede of Ann Arbor, Michigan; second vice-president, Edmund Souchon of New Orleans, La.; secretary, Herbert L. Burrell of Boston; treasurer, George R. Fowler of Brooklyn, N. Y.; recorder, De Forest Willard of Philadelphia; member of the council, W. W. Keen of Philadelphia. Place of meeting, Washington, D. C., in conjunction with the Congress of Physicians and Surgeons; time, May 1, 2, and 3, 1900.

NOTABLE BOOKS.

DAS BECKEN (THE PELVIS), VON W. WALDEYER.[1]

THIS work on the pelvis by one of the greatest living teachers and investigators of anatomy cannot fail to attract wide attention. The subject is an important one. A complete and accurate knowledge of the anatomy of

[1] Das Becken. Topographisch-anatomische mit besanderer berücksichtung der Chirurgie und Gynäkologie dargestellt von W. Waldeyer, M.D., Ph.D., Professor der Medicin und Director der Anatom. Institute, Berlin. Bonn: Fr. Cohen, 1899.

the pelvis is essential not alone to obstetrics and gynecology, the topics first naturally thought of in this connection, but to the surgery of the rectum, the bladder, and the various lesions, so common in this region, of the bony and soft tissues.

Though written by a professional anatomist, the book is far from being a dry digest of anatomical details; it gives in condensed and very practical form all the scientific medical knowledge we have up to the present time concerning not only the structures contained within the pelvis and their relations, but also its external coverings. This work is consequently a most useful one for the material it contains, and the method of its presentation is worthy of its contents. Original illustrations have been made from specimens furnished by such distinguished specialists as Testut of Lyons, Devy of Paris, Fritsch, Gusserow, Nagel, Nitze, Olshausen, Krause of Berlin, von Recklinghausen of Strasburgh, Gerota of Bucharest, and others. Altogether, the book is one of the most notable medical books of recent years.

Under the classification of pelves there is a very complete and suggestive discussion of the differences that have been noted, according to race, age, and sex, and the value of these peculiarities as regards ethnology and anthropology, as well as the more practical questions that sometimes come up for decision in medico-legal matters. In the discussion of the shape of the pelvis attention is called to the fact that it bears a definite, readily recognizable relation to the shapes of the heads of the races in which the different varieties occur. Sir William Turner's terms for their classification which are analogous to the corresponding cranial terms in anthropology are adopted. The Dolicho pellic, or long, oval pelvis, is found among the Australians, the Bushmen, the Hottentots, etc.; the mesati pellic, or almost circular pelvis, among the Africans and the Tasmanians, and in New Caledonia and Melanesia; the platy pellic, or broad, oval pelvis, is found among the Europeans, the Mongolians, and the Indians.

There is an excellent practical discussion of fractures and dislocations of the bones of the pelvis, and of tumors pertaining to this region both within and without the pelvis. Under fractures there is a report of a case that was found recently in the anatomical rooms of the University of Berlin in which the anterior bladder-wall had been forced into the space between the two fractured ends of bone as they sprung apart during the application of the fracturing force, and was retained there by the resilient pressure of the bony arches after the violence had ceased to act. It is a complication whose occurrence has been suggested on theoretical grounds, but this is, we believe, the first actual case reported.

Under the head of tumors external to the pelvis, comes the series of bursæ that may in following a special trade or occupation become chronically enlarged in the pelvic region, or that may, after chronic enlargement has existed for some time, become infected and suppurate. There is the organ-grinder's bursa, the bursa subcutanea trochanterica, situated just over the trochanter, and which becomes enlarged because of the irritation set up by the rubbing of the arm as it passes the hip in its frequent revolutions. There is the bursa subcutanea sacralis over the sacrum which enlarges in chimney-sweeps from the friction in ascending and descending chimneys. Then the bursa over the anterior superior iliac spines, which enlarges in weavers from the constant repeated impact of the "throw" of the loom. In English it is customary to call the enlargement of the bursæ over the tubera ischiadica weaver's bottom (sometimes irreverently referred to by the medical student as student's bottom). Professor Waldeyer, however, reserves for this bursary enlargement over (or under) the ischiac tubercles the name of turner's (drechsler in German, *i. e.*, wood-turner or carver) bottom.

With regard to the bladder and its relations to the ureter and kidney, some recent interesting work from various sources mutually confirmatory of certain newer views in this matter is given. The possibility of liquid being forced from the bladder into the ureter and thence to the pelvis of the kidney is admitted. Under pathological conditions, as with an over-distended bladder, this is not so difficult to understand. But even with a not over-distended bladder, when that viscus is somewhat hypertrophied, and its muscular fibers have been irritated into an easily excitable condition, liquid may thus be forced backward in the urinary tract. In healthy animals this has been demonstrated experimentally a number of times, and by various observers. The importance of this can scarcely be overestimated, especially since we have of late learned that it takes but a comparatively slight amount of pressure in the renal pelvis above the general blood-pressure at the moment, to force the renal filter, and send back into the circulation excrementitious products.

With regard to the possibility of absorption in the bladder itself, Waldeyer rather leans to the view becoming so general of late that it does take place to a limited degree. He points to the spread of neoplasms along the vesicular-lymph channels as a confirmation of this view.

He considers that though morphologically the posterior urethra and bladder are one, this portion of the urethra must not be thought part of the bladder in the urinary function. The internal sphincter of the bladder has been observed to be closed even under high pressure in the bladder of the living animal. Urine that finds its way into the posterior urethra is extruded completely by the micturition reflexes set up. There is an interesting discussion of injections into the bladder by forcing the muscles of the anterior urethra. Rectal and uterine and vaginal tissues and functions are discussed in the same practical scientific manner.

REVIEWS.

THE AMERICAN YEAR-BOOK OF MEDICINE AND SURGERY. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in All Branches of Medicine and Surgery, Drawn from Journals, Monographs, and Text-Books, of the Leading American and Foreign Authors and Investigators. Collected and Arranged un-

der the general editorial charge of George M. Gould, M.D. Illustrated. Philadelphia: W. B. Saunders, 1899.

Since the initial appearance of this Year-Book of Medicine and Surgery, in 1896, each succeeding volume has been received with even more favor than its predecessor. In these busy days it manifestly is impossible for the active practitioner to glean his knowledge of the rapid progress along special lines from the multitudinous publications issued for his benefit, and, therefore, it will be with a feeling of great satisfaction that he turns to this volume, in which he may find the facts boiled down and served with clear and concise editorial comments which add greatly to their value. In a weekly journal it is impossible to review in detail the many valuable features of a work of this magnitude; like all encyclopedias it must be studied by the individual in order that its many points of excellence may be brought out.

The data concerning typhoid fever and the Widal test is exceptionally complete. Regarding the latter the editors of the section sum up by saying: "Statistics show beyond question that the serum-test gives a positive result, sooner or later, in practically all cases of typhoid infection, and a negative result in cases in which typhoid infection is not present, and has not existed in the patient examined. . . Another fact that must be recognized is, that the Widal reaction often fails during the first week of the disease, and sometimes much longer. Repeated examinations are necessary in every case." Continued good results from the Brand method are reported. The Woodbridge treatment is condemned, and statistics presented to show that its claims to abort an attack are not deserving of consideration.

The advances made in the prophylaxis and treatment of pulmonary tuberculosis are reported in considerable detail. Work done in connection with the production of an antitoxin against yellow fever is reported, as well as improved methods in diagnosis and treatment.

The review of the diseases of the stomach and intestinal tract is especially satisfactory. Under the caption, "Anesthesia," it is said that the records are strongly against the use of chloroform as a routine anesthetic. In 22,219 chloroform-administrations there were 14 deaths, while in 17,067 administrations of ether, or gas and ether, there was 1 death.

Halsted's method of intestinal anastomosis is graphically illustrated, as is that of Laplace. Modifications of the Murphy button are pictured and described. The X-ray in diagnosis is given a prominent place and all that is newest in connection with this invaluable agent recorded.

The remaining chapters are devoted to gynecology, pediatrics, pathology, nervous and mental diseases, orthopedic surgery, ophthalmology, otology, diseases of the nose and larynx, cutaneous diseases and syphilis, materia medica, physiology, legal medicine, public hygiene and preventive medicine, and physiological chemistry, and each covers the ground in a very complete and satisfactory manner.

The book contains 1102 pages, is admirably indexed, and has a number of full-page plates, some in colors, and numerous illustrations in the text. Taken all in all it is invaluable in the special field which it aims to cover and the busy practitioner cannot afford to be without it.

Die Technik und der Comfort der Ernahrung. (Technical Methods of Conveniently Feeding the Sick.) Von Dr. Martin Mendelsohn, Privat-docent der inneren Medicin an der Universität Berlin. Leipsic: George Thieme, 1898.

The author of this little brochure, which is a reprint from Leyden's well-known work on the diet and feeding in disease, has written some interesting books on the technics of nursing and other subjects, closely connected with the treatment of patients other than by drugs. The work under consideration deals with the proper preparation of food for the sick and the manner of giving it to patients. The temperature of the nutritive material and methods of keeping it at any temperature, a discussion of dry, soft, fluid, and solid diets, a description of apparatus for feeding the sick at any stage of convalescence, apparatus for changing the position of patients in bed, and a consideration of the patient's surroundings while eating are the topics which the author handles with evident knowledge and certainly with skill. The little book contains much that is interesting and much that is valuable, and is well illustrated.

THERAPEUTIC HINTS.

Treatment of Eczema by Ointments Containing Sugar.—Hodara of Constantinople uses for cases of moist eczema, impetigo, ecthyma, subnasal sycosis, and other skin diseases of vesicular or pustular nature, an ointment of zinc oxid and sulphur containing sugar, the desiccative and keratoplastic properties of which he highly values.

℞ Sacchari pulv.
Zinci oxidi
Lanolini
Vaselini } aa . . . Parts xx
Sulphuris sublim.
Glycerini } aa . . Parts x.

M. Ft. unguentum. Sig. External use.

For subnasal sycosis he advises continuous application of the ointment to affected parts of the upper lip, and in addition repeated swabbing of the nasal mucous membrane with a solution of silver nitrate, at first one per cent. gradually increased to four per cent. As improvement advances the ointment may be used but once a day, but swabbing should be continued for a time after the cure is completed to avoid a relapse. Hodara has thus effected cures without epilation.

For seborrheal eczema of a psoriaform type he prescribes as follows:

℞ Sacchari pulv. . . . Parts xx
Chrysarobini . . . . Parts i–ii
Glycerini
Sulphuris sublim. } aa . . Part x
Lanolini
Vaselini } aa . . . . Parts xxx.

M. Ft. unguentum. Sig. External use.

THE MEDICAL NEWS.

VOL. LXXV. NEW YORK, SATURDAY, JULY 15, 1899. NO. 3.

ORIGINAL ARTICLES.

THE TREATMENT OF SUMMER DIARRHEA IN INFANTS.[1]

BY HENRY DWIGHT CHAPIN, M.D.,
OF NEW YORK.

THE treatment of summer diarrhea in infants naturally may be considered in three parts: preventive, dietetic, and medicinal. In order to appreciate the importance of preventive management it may be well to glance at some of the well-known causative factors that are in constant operation during warm weather. In the first place, all the varieties of diarrhea seen during the year are increased and aggravated in summer. The various mistakes so commonly seen in the feeding of infants take the front rank as causes. Gastric or intestinal indigestion usually precedes a diarrhea. Too frequent feeding, either at the breast or bottle, is a common underlying cause of infantile indigestion. When the bottle is used a larger amount of fluid than the infant's stomach can comfortably hold or digest is very often given. Cow's milk is not properly modified to suit the infant's age and digestion in many cases, or various foods containing large amounts of starch or sugar are employed. With the advent of hot weather the various kinds of infantile indigestion are liable to take on a dangerous diarrheal form. This is due to an acute fermentation or putrefaction of the gastro-intestinal contents, with the consequent absorption of toxic substances which quickly induces grave, if not fatal, symptoms. The heat of summer first depresses the vitality and weakens the resisting power of the infant, and then induces subtle and dangerous changes in the cow's milk which is its common food. The degree of heat required to start an epidemic of summer diarrhea seems to be fairly constant. Some years ago Dr. Seibert, in studying this subject, showed that an epidemic would start when the average minimum temperature reached 60° F. This condition begins in June and lasts through September, which are thus the dangerous months. The accompanying table shows the number of deaths from diarrheal diseases in New York City during the past five years in children under five years of age, through the summer months, with the mean temperature of the corresponding periods.

A glance at this table shows that July gives much the highest death-rate, and the average mean temperature of this month is from one to four degrees higher than August. The slight difference in temperature, however, is not sufficient to account for the much higher mortality. In 1895 it will be seen that the mean temperature of August was three degrees higher than July, which is most exceptional for summers in this latitude, and yet the mortality of July was 1084 against 633 for August. The explanation is that after several weeks of warm weather the weaker babies die off. Hot weather usually begins late in May or early in June, so that by July there has been a month of fairly continuous heat. After several days of very great heat, the severe diarrheas begin, often when the temperature has had a distinct and grateful fall.

DEATHS UNDER FIVE YEARS.

When the baby feels the greatest depression from the heat the deleterious changes in the cow's milk are most marked, hence bottle-babies are by far the greatest sufferers. Not only does the lactic-acid fermentation begin, but various colonies of bacteria are multiplied, such as the saprophytes or those of the proteus group. Infants under two years are the greatest sufferers. Preventive treatment, if carried out with thought and thoroughness, will do much to alleviate this annual summer scourge. Such treat-

[1] Read at a general meeting of the New York Academy of Medicine, June 1, 1899. For discussion see page 87.

ment will include in its scope an oversight of the city, the domicile, and the life and habits of the children. The responsibility of the city is to be doubly watchful in the interests of public health. The streets must be kept scrupulously clean. All garbage and decaying animal and vegetable matter should be promptly removed and destroyed. Perishable food stuffs, and particularly cow's milk, require careful watching and regulation. While milk with a certain minimum proportion of cream is now called for there should be a certain standard of freshness required as well. The number of bacteria found in each cubic centimeter of milk usually bears a direct ratio to the age of the milk. What is needed is a better regulation of a city's milk-supply at its source, namely, the dairy-farm. If the dairy farmer were compelled by government rules carefully laid down and enforced to regulate the production and handling of milk according to cleanly and scientific principles, and such milk could be delivered to the consumer within twelve hours. summer diarrhea in infants would be reduced to a minimum. In a city like New York, which draws its milk-supply from such a wide area and from great distances, it would be difficult to devise a scheme of milk inspection on the lines above noted that would be practicable, but it is the goal to be sought for. If city infants could be supplied with a clean and fairly fresh milk, the illness and mortality from summer diarrhea would lessen in a very marked degree. In this connection it is interesting to note the report that the city of St. Paul now requires an official inspection of all cows from which the milk supply for that town is taken.

Another way in which the city can modify the deleterious effects of the heated term is by planting trees and furnishing small parks and breathing-places for infants and little children. In a thoughtful and suggestive article, entitled "Vegetation a Remedy for the Summer Heat of Cities," in the *Popular Science Monthly* for February, 1899, Dr. Stephen Smith shows how trees are of the greatest utility in modifying and equalizing climatic conditions. He states that it is a well-established fact that an average temperature of the air of 54° F. is best adapted to public health, as at that temperature the decomposition of animal and vegetable matter is slight, and normal temperature is most easily maintained. Every degree of temperature above or below this point requires an action of the heat-regulating power to maintain a proper equilibrium. As the heat-regulating centers in infants and young children are most unstable, the direct action of prolonged heat upon their bodies is a powerful agent in increasing summer mortality from all kinds of illness. In a large and densely populated town the solar heat is conserved and reflected by the stone and asphalt of the streets as well as by the bricks and mortar of buildings. The artificial heat generated in the latter for culinary and manufacturing purposes is also a factor to be considered. Even during the night the stones by retaining their heat prevent any fall in temperature, sufficient to afford relief. Here is where the modifying effects of trees would be most beneficial. As trees maintain an average mean temperature of 54° F. in all seasons, it is easy to see what a constant cooling influence they would possess in an atmosphere of 90° F. Add to this the constant exhalation from the leaves of watery vapor that has been absorbed from the moisture in the soil as well as from the surrounding air, and the cooling effect is much enhanced. This takes place most actively during the heated portion of the day when it is most needed. A general purification of the air is not the least benefit to be derived from vegetation, as CO_2 is absorbed and O given out, just the reverse of what takes place in the animal economy. The purifying and cooling influence of trees placed uniformly through the city would have a marked influence upon the public health, especially that of little children. The Tree Planting Association of New York has proven that various species of trees are adapted to our soil, and, with a little care, can be made to thrive. It seems, however, in a matter that concerns not only the health but the beauty of the town, the city itself should be responsible for a uniform and continuous effort. If our blazing thoroughfares were lined with shade trees, the summer heat would not be so intolerable and unhealthful to adults and children alike.

Much may be done in the domicile, to prevent diarrhea among the infant inmates. The principal efforts will be in the line of extra cleanliness. Food of all kinds must be removed when the meal is ended. Milk must be boiled or pasteurized as soon as it is delivered in the morning, then properly diluted or modified in bulk for the day and placed upon ice ready for use. The less it is handled after this the better. All diapers as soon as removed should be soaked in a solution of chlorid of lime or similar disinfectant, before being washed. By keeping the rooms well closed during the heat of the day and freely aired at night, some equalization of temperature will result.

Preventive treatment can attain brilliant results in a watchful oversight of all the hygienic details of the infant's life. Mothers, particularly among the poor, should be taught to consult physicians oftener with reference to preventive agencies, especially when threatened by an epidemic of summer diarrhea.

Babies are often dressed too warmly and with needlessly tight-fitting garments in summer. In very hot weather a single garment is often sufficient as it is comfortable and cooling to be able to freely move the arms and legs. Plenty of fresh air can be had early in the morning and late in the afternoon without exposing the infant to the heat of midday, even in the shade. While trips to the seaside are healthful care must be exercised in reference to day excursions where heat and fatigue or slightly spoiled food may do more harm than the fresh air will do good. It is here assumed that the parents are unable to give the infants a change to the seaside or country, which, of course is highly desirable. In case a change of air is feasible for a bottle-baby, a locality where the milk-supply is known to be good must always have the preference. Frequent bathing is valuable in prophylaxis. In dispensary practice I often direct mothers to let little children be put in a tub and play in tepid water for several hours. Both the temperature of the air and that of the body are highest in summer from about two to five in the afternoon, and this is the time they are stripped and allowed to play in the water. The effects of the heat at the worst part of the day are thus neutralized. Babies too small for the tub may be sponged with water to which alcohol or vinegar has been added. In reference to diet very explicit directions must be given. *In general, a bottle-baby should have less bulk of food and a higher dilution of milk in very hot weather* than it is accustomed to under more favorable conditions. If this simple precaution were taken much summer diarrhea would be avoided. The intervals between feedings may also be prolonged if the digestion shows any signs of derangement, but water is to be freely given during these intervals.

With reference to milk, I prefer boiling or pasteurization to sterilization. In case of prolonged and intense warm weather, sterilization may temporarily be preferable.

The final effort of preventive treatment is to note the first signs of gastric or intestinal indigestion, as both may often be checked by simple dietetic or medicinal means before a marked diarrhea begins.

In the dietetic treatment of summer diarrhea, bearing in mind that a majority of the cases consist largely of milk-poisoning, all forms of milk must be temporarily withheld. Even the breast may be withdrawn in nursing babies until vomiting ceases. In the interval, water may be frequently given, but in small quantities at a time, if the stomach tends to reject it. The common mistake is in giving too much nourishment at this time, as the infant seems to be weak and in need of support. It is not the food taken, but that which is assimilated that supports, hence it is folly to force milk upon a baby at a time when the digestive powers are weakened, if not entirely arrested. Many a summer diarrhea would be stopped at the very beginning if milk were entirely withheld for from twelve to forty-eight hours. When it is necessary to withhold milk for any length of time, other forms of nourishment may easily be substituted. One of the most easily procurable and satisfactory is egg-water. The white of an egg is thoroughly stirred in half a glass of cool water. This forms a pure and easily assimilable albumen water. The only objection is its tastelessness, and I have overcome this by the addition of about ten drops of aromatic spirits of ammonia. In case there is a tendency to vomit, this aromatic stimulant in small doses, as above, seems to check the stomach irritation. Among other substitutes for milk may be mentioned thin gruels made from barley or wheat flour and cold whey. When the cereals are used, the starch may be easily dextrinized by one of the preparations of diastase that are now on the market. If cow's milk is withheld for several days or longer, mutton-broth from which all the fat has been carefully skimmed, makes a good substitute. Expressed beef-juice with the fat removed and diluted with cool water makes a stimulating and nourishing drink. When the acute symptoms have subsided and milk is resumed, it must be tentatively begun at long intervals and with high dilution. If a prescription to be filled at a laboratory were written it might call for fat, 1 per cent.; sugar, 4 per cent.; proteids, 0.50 per cent.; or plain fresh milk may be diluted five or six times with sugar-water. By thus starting with a considerable reduction of the casein and fat, these solids may be gradually increased to a proportion that is proper for the infant's age and development. The difficulty of digesting the tough curd of cow's milk is a constant source of trouble. After trying various methods of overcoming this difficulty, a proper dilution of the milk with decoctions of the cereals as advised many years ago by Jacobi, has yielded the best results in my hands. In hot weather a gruel made of wheat or barley flour, and partially or completely dextrinized, will modify and attenuate the clots of casein in a favorable manner. In a series of experiments recently made through the courtesy and with the cooperation of Professor Graham Lusk at his laboratory in the University Medical School, liquid rennet was added to various preparations of milk and heated to 40° C. Equal parts of barley-water and milk gave smaller and more flocculent curds than equal parts of plain water and milk. A dog with gastric fistula was fed on consecutive days with these solutions, and the contents of the stomach withdrawn at the end of half an hour. The

clots were finer and apparently more digested when the barley-water and milk was used than in the case of plain water and milk. Aside from the results of such experiments, the clinical effect of diluting with the gruels must commend their use. Babies are less apt to vomit tough, stringy curds, or to pass them by the bowel.

The medicinal treatment usually assumes less importance in direct proportion as the preventive and dietetic management are carefully followed. Indiscriminate and abundant drugging in this disease are now relegated to the limbo of the past, astringents, antiseptics, and opiates alike. The real indications for drugs are few and easily apprehended. As summer diarrhea is so apt to be of a putrefactive nature, all agree upon the necessity of completely clearing out the gastro-intestinal tract as a necessary start in treatment. In most cases, when the physician is called, the stools are loose and there may be vomiting. By at once stopping all milk, the stomach is soon emptied, and the principal indication is to clear out the bowel. If vomiting continues, drafts of tepid water may be administered, which, when rejected by the stomach, washes out that organ. I do not believe it is often necessary to wash out the stomach with the tube. Sometimes when there is excessive irritation of the stomach, with much production of mucus, one washing out, however, will give relief. I usually employ tablet triturates of calomel, $\frac{1}{10}$ of a grain every hour until six or eight have been administered. These small doses act as a sort of stimulant to the bowel, increase glandular secretion and usually effectively clear the canal of its fermenting contents. The drug is also supposed to have some antifermentative effect. A good sized dose of castor oil is also effectual, and is followed by a sedative effect on the mucous membrane. If the stomach is very irritable, it may be difficult to administer on account of vomiting. Elimination may sometimes be hastened by irrigation of the lower bowel with normal salt solution. Mucus as well as fermenting milk may be thus removed. For those not accustomed to this procedure, a hard rubber rectal tube is preferable, as the soft tube bends on itself on account of the length and marked curve of the sigmoid flexure in infants. The drug that I have found most useful in the summer diarrhea of infants is the subnitrate of bismuth in large doses. As far as I have observed the subcarbonate, salicylate, and subgallate of bismuth and beta naphthol bismuth have no decided advantage over the subnitrate, which is everywhere procurable. A baby of from six to twelve months can take from ten to twenty grains of the subnitrate every two or three hours. The insoluble quality of the bismuth and its sedative local effect make it most valuable. Irritation and fermentation, even under proper dietetic management, remain longest in the ileum and colon and this tract is reached by the local action of the bismuth.

Most of the so-called antiseptics have irritating qualities, and I do not think that even in antiseptic action they act better than large doses of bismuth. It is manifestly impossible to put the intestinal tract in any condition that can be called antiseptic by the administration of drugs. Small doses of aromatic spirits of ammonia, 10 to 20 drops, well diluted with water, seem to stimulate the mucous membranes and refresh the infant. I give alcohol very sparingly in these cases as it seems to lower the digestive powers. In case of great weakness or collapse from 10 to 30 drops of whisky may be given well diluted. Formerly I gave whisky almost as a routine treatment in these summer diarrheas, but now it is used only for special indications and temporarily. If the discharges are profuse and exhausting and the baby sinks into a semi-stupor, with depressed fontanelle, very free stimulation by whisky and ammonia is indicated, as spurious hydrocephalus is thus ushered in. There is one drug that was formerly much abused and is perhaps not used enough now in proper cases, namely, opium. It should never be given combined with other drugs; indeed, diarrhea mixtures of all kinds are to be deprecated. Opium is contraindicated until the bowel has been thoroughly emptied of irritating contents, when the stools are scanty and foul-smelling and when cerebral symptoms threaten. In cases, however, in which rapid peristalsis and profuse glandular secretion persist, a few moderate doses of opium are most valuable and may aid in saving life.

The order of importance in treatment is that sketched in the preceding portion of this paper: first, prevention; second, careful dieting, and, finally, drug administration. If the first two are carefully carried out it will not so often be necessary to employ medicines.

HIGH ALTITUDE AND HEART DISEASE.[1]

By ROBERT H. BABCOCK, M.D.,
of Chicago, Ill.

My attention was first attracted to this subject years ago by the following interesting case: In November, 1886, I was consulted by Dr. N., a practising physician in the interior of New York State, who was on his return from Colorado. He was a powerfully built man of five feet nine inches in height, and 185 pounds in weight. Until October,

[1] Read at the fourteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

1885, he had enjoyed robust health, and prided himself on his strength and feats of physical endurance. He then one day carried a barrel of flour up stairs on his shoulders, and on reaching the top was seized with precordial pain and palpitation. From that time his health failed, a slight dry cough developed, and once he expectorated a little blood. This led him to consult two eminent physicians of New York City, one of whom diagnosticated incipient tuberculosis of the right apex, while the other pronounced the examination negative. Both, however, advised him to go to Denver, which he did in June, 1886. Upon reaching an altitude of 2000 feet *en route* he began to experience considerable distress in the chest, and on arriving at Denver, at an altitude of 5300 feet, he was almost, as he stated, in convulsions. During his six-weeks' stay his dyspnea and precordial distress were so great that he at length consulted Dr. Dennison, who, he said, found his lungs normal, but demonstrated marked dilatation of the right ventricle. The advice was given to seek a lower altitude, and the patient went to South Dakota, where the elevation was but 1500 feet. His symptoms gradually left him, and after a few days he was able to ride horseback without discomfort.

This was about the middle of August, prior to his appearance at my office. My records, made after two examinations on successive days, state in brief that the lungs were normal, but that there was a short, rough presystolic and a faint blowing systolic apex murmur with accentuated pulmonic second sound and increase of dulness to the right. The pulse was somewhat accelerated, feeble, and slightly irregular. I made a diagnosis of mitral stenosis and insufficiency, either resulting from or aggravated by the unwise physical effort of the year before, and which accounted for the unexpected ill effect of high altitude. I have never heard from the patient since that time.

CASE II. is that of Dr. W. H. B., whom I first examined in February, 1887, making a diagnosis of fatty degeneration, chiefly of the left ventricle, due to coronary sclerosis and accompanied by attacks of angina pectoris. In November, 1887, he reported himself as well except for inability to walk rapidly on account of dyspnea. During the summer of 1889 he made a trip to Alaska, concerning the advisability of which he had consulted me, and against which I had urged the necessity of his being subjected to considerable risk in traveling over high mountains on the Canadian Pacific Railroad. Upon his return, however, he reported that at an altitude of 7000 feet he had been able to walk without any discomfort whatever.

That serious structural disease existed is attested by the sad fact of his sudden death the following May, 1890, in an attack of angina pectoris at the age of seventy-three. No necropsy was made; but during life the somewhat thickened arteries and accentuated clapping aortic second sound had left no room for doubt of the existence of arteriosclerosis and resulting myocardial changes.

CASE III.—About ten years ago one of my uncles, then seventy-two years of age, visited me *en route* to Denver to pass the summer. His radial arteries felt like a string of beads, and he had secondary left-ventricle hypertrophy, the heart still being competent. I greatly feared the effect of Denver altitude, and cautioned him accordingly; and yet he subsequently reported that while there he had been able to walk without the slightest inconvenience. If he had noticed any effect from the altitude it had been for the better.

CASE IV., like the one immediately preceding, is reported from memory, as no notes were ever made. The late Dr. S. of Chicago, whom it was my privilege to know intimately, once drew my attention to a loud mitral systolic murmur which he said he had had for years, but without particular symptoms. The circumstance that impressed my memory at the time was his comment to the effect that notwithstanding that murmur, which he regarded as indicative of valvular incompetence, he had just made a trip to Colorado Springs, an altitude of 6000 feet, and had been able to walk about with less discomfort than his wife, who so far as he or anybody else knew possessed a healthy heart. This lady was rather short and inclined to corpulence, it may be remarked in passing. The doctor at that time was about sixty years of age.

CASE V.—H. P., aged twelve years, was seen in June, 1892, one month subsequent to an operation for appendicitis during convalescence from which anasarca and other signs of destroyed compensation of a long-standing mitral lesion had appeared. At the date of my visit digitalis and other appropriate treatment had begun to restore cardiac competence, and my opinion was desired upon the advisability of the boy's return to his home in Trinidad, Col. At the age of six years, while resident in that place, he had suffered from acute articular rheumatism, and then for the first time had been found to have a mitral lesion. During the next four years he had been in tolerable health, but had not been able to play with other children because of cardiac symptoms. Two years before my examination he had again suffered from rheumatism with pleuritis and pericarditis for which the precordia had been blistered. Nevertheless, he had been able to remain at Trinidad, at an

elevation of 6000 feet, until the development of the appendicitis.

Upon examination I discovered mitral regurgitation with great secondary dilatation, pleuropericardial adhesions, and old pleuritic adhesions at the base of both lungs, and great visceral engorgement. Of course the advice was given not to return to Trinidad, where his tuberculous father was residing. The patient passed the remainder of the summer of 1892 in Canada, and I believe regained such a measure of compensation that during the fall of that year he was taken back to Colorado. I did not see the boy again, but have since learned indirectly that he failed progressively thereafter, and died about four months after his arrival there.

Case VI.—During the summer of 1894 an attorney, aged forty years, consulted me for an opinion concerning the state of his heart, and, briefly stated, was found to have a pronounced but perfectly compensated insufficiency of the aortic valves. He furnished the following interesting history: He had but shortly before returned from a two-weeks' visit in Colorado, where at the altitude of Denver and Colorado Springs he had ridden about on his wheel without any discomfort. One day he attempted the ascent by train of Pike's Peak, which has an altitude of 14,137 feet. Distress became so great that he was in collapse by the time the summit was reached. The descent was made at once; his consciousness returned before he reached the foot, and when again at the altitude of Colorado Springs he mounted his bicycle and rode away, apparently none the worse for his foolhardy adventure. I have not seen the patient since my first examination.

Case VII.—At the present writing I have in charge a lady aged about forty years, who has been in bed for the last four months in an attempt to preserve from total loss what still remains of a rather inadequate compensation of an extreme aortic stenosis. She has known of her cardiac lesion for the past seven years. Although she had been cautioned against high altitudes she was compelled about five years ago to accompany a tuberculous stepson to New Mexico. At first they went to Colorado Springs, where they remained a month. There she was not able to walk more than a few hundred feet without sitting down to recover breath. For some reason they then went to Sante Fé, 7000 feet, but remained only two days because of the great distress occasioned to the lady. In consequence they next traveled to Eddy in the Pecos Valley, where she was able to stay until the young man's death, two years subsequently. While there, at an elevation of about 3000 feet, the lady experienced no particular discomfort, being able to walk about the house and grounds without dyspnea. She is positive that she has never been as well since her sojourn in New Mexico, and in fact was compelled to seek medical advice for her cardiac asthenia soon thereafter.

Case VIII. is that of a lady, aged sixty-eight years, who, immediately before consulting me, had endured the railway journey from San Francisco to Chicago over the Sierra Nevada and Rocky Mountains. At the summit of the former, 7500 feet, and again at Hagerman Pass, 11,500 feet, she suffered considerably from difficulty in breathing, but at Colorado Springs she experienced no discomfort. Nevertheless, she thought it prudent to sit still in the car and not attempt walking. This patient had a pronounced mitral systolic murmur and great sec ondary cardiac dilatation, particularly of the right auricle, as shown by the turgid external jugular veins and by percussion. There was evidence also of arteriosclerosis; and as the pulsations of the thin-walled and probably dilated aorta were visible in the suprasternal fossa and communicated to the distended veins, the erroneous diagnosis had been made of aortic aneurism. Rest in bed, aided by the administration of strophanthus and cathartics, lessened the cardiac dilatation markedly and more promptly than I had dared to hope for, and soon thereafter I lost sight of the patient. Six months later she died in charge of a homeopathist, who, I was told, said she developed an ovarian cyst.

Case IX.—Last summer Miss N., aged twenty-one years, was referred to me by Dr. Minor of Asheville, N. C., because she had not been able to endure the 2500 feet altitude of Asheville, and had to return to her home in Chicago. She stated that she had been forced to leave there on account of the dyspnea experienced whenever she attempted to do any walking, although such had not been the case when there two years earlier. Examination disclosed free mitral regurgitation, and in addition extensive adhesions between the pericardium and left pleura, as shown by retracted lung border and friction râles on inspiration. The apex was fixed in the sixth left interspace fully two inches outside of the mammary line. The right heart was not bound down. Hepatic and other visceral engorgement was extreme, and disappeared on appropriate treatment, with the lessening dilatation of the right ventricle. But the ready dilatability of the right heart has its bearing on the patient's inability to endure the moderate altitude of 2500 feet.

Of course I realize that nine cases afford altogether too slender a basis on which to build a theory regarding the effect of high altitude on the heart and circulation, but they seem to me worth a few minutes study in the hope that they may aid us in

deciding the question whether or not the existence of heart disease always prohibits residence or travel in elevated regions. That such is the case is the general opinion, I think, an opinion in which I formerly concurred.

Regnard, on the contrary, thinks that cardiac lesions *per se* do not contraindicate sojourn at high elevations when such residence is necessary; yet he would not advise it because there is nothing in the condition of health of these patients demanding such climatic treatment, in fact, hematosis would be diminished; but aside from this no harm would result from the decreased blood pressure; and if a cardiac sufferer chose to endure the discomfort he would at first experience until he became acclimated, he could do so with impunity. Regnard evidently bases his opinion on the study of the phenomena of mountain sickness which his experiments have led him to attribute not to diminution of blood pressure, but to want of sufficient oxygen supplied to the tissues and organs—"*l'asphyxie des tissus survient.*"

Although such may be the explanation of mountain sickness, I, nevertheless, think that Regnard's view regarding the effect, or rather, want of permanent effect on heart patients, is too sweeping, as some of my foregoing cases show. There is a quickening of the pulse-rate, and this it is which I think must be reckoned with in considering the question of altitude in cardiac disease.

In an interesting paper in the London *Lancet* of October 15, 1898, Sunderland reports the arrest of menorrhagia at high altitude, 5800 feet, and suggests the explanation that by reason of diminished air pressure on the abdomen and in the lungs the large distensible veins within the peritoneal cavity become dilated,and thus favor a more rapid return flow of blood from the congested vessels within the pelvis. Unfortunately, this theory is untenable, since it must assume an expansion of the tissues in the walls and organs of the abdomen, and as Regnard argues, such an expansion of solids and fluids of the body is impossible when the entire surface of the body is subjected to uniform diminution of atmospheric pressure. It would be far otherwise if the vessels were filled with a gas instead of blood. Sunderland's explanation is correct only in part. The menorrhagia is arrested in consequence of more active circulation undoubtedly, yet this acceleration is not due to lessened blood pressure occasioned by essened air pressure, but I believe, to those modifications of the respiratory movements incident to owered atmospheric pressure.

According to Regnard the effect of high altitude is to quicken respirations at first and render them more shallow. When, however, the individual has become accustomed to the diminution of air pressure, the depth of respiration increases and may even exceed the average. That this increase in the depth and frequency of respiration must accelerate the blood-flow will become apparent upon consideration of the effect of respiratory movements on the circulation. Briefly stated it may be said that with each inspiration pressure falls within the two venæ cavæ in consequence of their contents being aspirated into the right auricle and ventricle. This latter chamber, therefore, receives and discharges an increased supply of blood into the pulmonary artery, while under the dilating influence of inspiratory expansion of the lungs the flow within the pulmonary vessels is hastened. The consequence is that toward the height of inspiration and during the fore part of expiration a larger volume of blood is discharged into the aorta and pressure within this vessel rises. During the latter part of expiration and in the beginning of inspiration, on the contrary, the reverse obtains. If now respiratory movements be quickened and deepened, as at high altitudes, the rate of the heart's contractions must undergo a corresponding acceleration.

Another factor in hastening the flow of blood to the heart is the action of the diaphragm. According to physiologists, the descent of this muscle by diminishing the size of the abdominal cavity causes an upward flow of blood out of the abdominal veins into the inferior vena cava and thus exerts a pumping action. It is evident, therefore, that herein lies another by no means insignificant explanation of the beneficial effect of the high altitude in Sunderland's cases of menorrhagia.

That an acceleration of the circulation is not merely theoretic is substantiated by the statement of Regnard and others who declare that the pulse may reach even 130 or 140 beats to the minute. Furthermore, Regnard reproduces three sphygmographic tracings which show a diminution in the size as well as increase in the rate of the pulse at an elevation of 1050 meters, while at the summit of Mont Blanc, 4810 meters, the smallness of the pulse becomes still more pronounced. Now this diminution of the pulse must be due either to engorgement and weakness of the right ventricle, in consequence of which it discharges an abnormally small volume of blood into the pulmonic system, or to the fact that the heart in its entirety handles a small amount of blood with each cardiac cycle. The former hypothesis is untenable, since it is at variance with the effects observed in menorrhagia. Stasis in the right heart would have led ultimately to increased engorgement of the uterine veins and capillaries and

thus have aggravated the condition. Therefore we must assume that the smallness of the pulse at the summit of Mont Blanc was owing to the rapidity of the cardiac contractions, while its diminution of tension was not due to dilatation of the arteries from lessened air pressure, but to the smallness of the blood-wave resulting from the rapidity of the heart-beats.

Let us see how this simple explanation can be applied to the foregoing nine cases. Cases II. and III. were instances of arteriosclerosis without valvular disease and in both arterial tension was consequently increased. This threw extra work upon the left ventricle, which in Case III. was adequately met by compensatory hypertrophy, while in Case II. the presumably degenerated myocardium was unequal to the task and dyspnea on exertion resulted. At 7000 feet, however, the quickened return circulation in the veins relieved pressure in the arteries, the weakened left ventricle found its work easier in consequence, and the patient could walk about without discomfort. For the same reason the third patient was able to spend the summer in Denver without consciousness of any difference between the altitude there and that of Cleveland, where he resided.

Cases IV. and VI. were instances of regurgitant disease, the one mitral, the other aortic, and both patients had experienced no difficulty from exercise at an altitude of about 6000 feet. The reason for this seems to me to lie partly in the diminution of arterial tension and partly in the relief felt by the left ventricle. Diminution of pulse tension would tend to lessen the force of the regurgitant stream in either case and thus lighten the work of the heart. In mitral incompetence the dilatation of the pulmonary vessels and quickening of the flow through them incident to deepened respirations would relieve the right heart, and it is conceivable that dyspnea might actually be lessened thereby. As in regurgitant lesions the tendency is for the pulse-rate to be quickened, the heart ought to find but little difficulty in adjusting itself to the acceleration of the venous flow occasioned by lowered atmospheric pressure, and I believe such is the case when complications do not prevent.

In Case VIII. there was free mitral leakage with a greatly distended right auricle, and yet the old lady suffered from dyspnea and cerebral congestion only at altitudes considerably higher than that of Colorado Springs. This must have been owing to her remaining seated in the car, so that notwithstanding the more rapid flow into the right auricle the resistance in front was lessened, as already explained, sufficiently to offset the increased discharge into the auricle. Had she attempted to walk about she would probably have felt very short of breath.

Cases V. and IX. were likewise examples of mitral insufficiency, but complicated by pericardial and pleural adhesions. Here were conditions that would obviously interfere with pulmonary expansion, and would occasion dyspnea under lowering of air pressure even without the existence of a valvular defect. There was probably some increased play of the diaphragm which promoted the flow in the inferior vena cava more rapidly than it could be disposed of by the hampered heart. In the young lady's case the adhesions binding down the left ventricle restricted its systole, while at the same time the unfettered right ventricle was free to receive and discharge its contents until the pulmonary system became surcharged and dyspnea resulted. In a word, pleural and pericardial adhesions furnish a mechanical hindrance to a proper adjustment of both respiratory and circulatory apparatus to a diminution of atmospheric pressure.

Case I. was an instance of mitral stenosis and Case VII of aortic constriction. In both an unyielding barrier to the blood flow existed, and time had to be allowed for the stream to pass the point of obstruction. In stenosis systole is slow and forcible so long as compensation is adequate. Acceleration of the circulation at high altitudes would quicken cardiac contractions; with the shortening of systole time would not be allowed for complete emptying of the chambers back of the constriction; stasis in the pulmonary vessels would be promoted with corresponding dyspnea that might readily grow urgent on exercise.

CONCLUSIONS.

1. All forms of cardiac disease do not contraindicate sojourn at a high altitude.

2. The ill effects of low atmospheric pressure in some forms of cardiac disease are explicable on the hypothesis of acceleration of venous flow and corresponding quickening of the heart beats.

3. Consequently those forms with which high altitude is likely to prove incompatible are pronounced aortic or mitral stenosis, and regurgitant disease complicated by pleural and pericardial adhesions.

4. On the other hand, patients with uncomplicated regurgitant lesions or arteriosclerosis with or without myocardial changes, may endure low atmospheric pressure without injury.

Yellow Fever in Mexico and Central America.—The epidemic at Vera Cruz is still spreading, about fifty new cases being reported each week. The mortality has been high, averaging about 47 per cent. At Panama 34 cases have been reported, with 18 deaths.

CYSTITIS; ITS CAUSE AND TREATMENT.

BY GEORGE T. HOWLAND, M.D.,
OF WASHINGTON, D. C.

THE different opinions that have been held, and continue to be held to a certain extent, as to the cause of cystitis, are many and varied. C. Monsell Moullin,[1] in his very interesting work, speaks correctly when he says, "It is better that the peculiarly misleading term, 'catarrhal cystitis' should be dropped." Melchior[2] states that while he does not deny the possibility of the occurrence of catarrhal cystitis, so far he has never met with it. Guyon[3] expressly states that there is no variety of cystitis that is not purulent. Cohnheim[4] also states that pus is always present in the urine in cases of cystitis, whether the inflammation is acute or chronic.

That the starting-point in cystitis is due to an infection, and that the disease is continued by the action of one or more of the various pathogenic micro-organisms, may be said to be an axiom as far as this disease is concerned. The easiest avenue through which an infection may occur is through the urethra, in which normally a number of different organisms are constantly present. Most of these organisms are non-pathogenic, but the colon bacillus is present in a very large proportion. It is still undecided whether the deeper portions of the male urethra, if healthy, harbors pathogenic organisms for any length of time. When the urethra has been altered by stricture or by enlargement of the prostate the chances of pathogenic organisms being able to maintain themselves in it are greatly enhanced. In women who have borne many children, in whom the urethra is dilated and patulous, an infection may occur by the organisms passing into the bladder from the urethra without the aid of instruments. In women the neighborhood of the meatus urinarius is never free from micro-organisms, and cultures of the colon bacillus mixed with others can nearly always be found. The bladder may also be infected from the kidney, either when the kidney or its pelvis is diseased, as in pyelitis or pyelonephrosis, or even when the kidney is healthy the organisms may be eliminated from the body through it and thus infect the bladder.

Reymond[5] has proven beyond any question that bacteria can enter the bladder direct from inflammatory areas in the neighboring organs. He found cystitis of frequent occurrence in women suffering from inflammation of the uterus or of the Fallopian tubes and in the majority of cases proved by culture that the organisms were the same in both organs. As an additional proof he found in a case of salpingitis in one tube a localized cystitis on the same side of the bladder. An infection may come from rupture into the bladder of purulent collections in other abdominal viscera, as for instance, tubal, ovarian or perityphlitic abscesses.

The direct predisposing cause of cystitis has not yet been fully determined. We know that pyogenic organisms may be present in a normal bladder and never set up cystitis. This has been proved by experiments both on the lower animals and on human beings. The typhoid bacillus and many other pyogenic organisms are excreted by the kidneys and pass through the bladder without doing it the slightest harm. This shows that the presence of bacteria alone is not sufficient in the normal bladder to set up an inflammatory reaction. It is well known that after a slight traumatism of the bladder wall cystitis nearly always results. Under this head we can place cystitis following catheterization and instrumentation of the bladder, also the cystitis produced by stone in the bladder. We also find cystitis accompanying the growth of either benign or malignant neoplasms of the bladder wall. The ingestion of irritating drugs, by their caustic effects on the vesical mucosa, prepare a suitable soil for the entrance of the bacteria.

A question at present receiving much important consideration is whether the gonococcus of Neisser is or is not capable of producing cystitis. The French observers believe that this germ cannot produce a true cystitis, yet a few cases have been reported which point to a pure infection by this organism. Krogus and Barlow[1] each record cases, as does Melchior, and more recently Wertheim[2] demonstrated before the Berlin Obstetrical and Gynecological Society a preparation from a case of gonorrheal cystitis which showed the capillary and precapillary veins filled with gonococci and a condition of gonorrheal thrombosis and thrombophlebitis. The cystitis was secondary to a gonorrheal vulvovaginitis and was associated with infection of both ulnar joints. The microscopic sections were made from a portion of the mucous membrane excised during cystoscopic examination. A small portion of the excised mucous membrane was placed in prepared blood-serum with the result that a pure culture of gonococci was obtained. Wertheim says, regardless of the statement of Guyon, Bumm, Sanger, and others (that a gonorrheal infection of the bladder is always a mixed infection), that the finding of gonococci alone in this case proves beyond

doubt that pure gonorrheal cystitis can occur. A gonorrheal thrombosis and thrombophlebitis had never before been demonstrated, and the writer believes that a step toward a better knowledge of this disease has been made. He says it is useless to seek for the gonococci except in the very acute stage as they very soon disappear. On the other hand, Bauzet, in a very interesting paper on this subject, makes the following statement: "The gonococcus of Neisser is not proved to have pyogenic properties, except as regards the mucosa of the urethra, the conjunctiva, and the female genital organs." I have seen a number of cases in which cystitis was present or followed directly after a posterior urethral gonorrhea, but I have never been able to find the gonococcus of Neisser alone; it was always accompanied by other pyogenic organisms.

The pathogenic bacteria which have been most commonly found in cystitis are the following: bacillus coli communis, streptococcus pyogenes, staphylococcus pyogenes albus, citreus, and aureus; bacillus lactis aerogenes, tubercle bacillus, gonococcus of Neisser (mixed infection), the typhold bacillus, and several varieties of the proteus. We may state that from our present knowledge the following facts may be laid down as the cause of cystitis:

1. Cystitis is always caused by the presence of bacteria.

2. The mere presence of bacteria is insufficient to cause cystitis; a further predisposing cause is necessary.

3. Under favorable conditions any pathogenic organism may give rise to cystitis.

4. The entrance of pathogenic organisms into the bladder may be through the urethra, through the ureter from an infected kidney, from inflammatory areas in the neighboring parts, and through the blood-stream and the lymphatics.

From what has been said in regard to the cause of cystitis it is plain that the prevention of this disease depends upon the avoidance of local congestion and of the entrance of the germs into the bladder. Local congestion may occur in spite of our best efforts to prevent it, and septic germs may enter the bladder from causes over which we have not the slightest control. It is seldom that we are called to see a case of cystitis in which these features are not already present.

Proper hygienic and antiseptic precautions are necessary in all cases of surgical interference in the urethra and bladder and all instrumentation in or about the urethra or bladder must be conducted under strict antiseptic precautions. The entire genito-urinary tract should be made as near aseptic as possible and this can be accomplished through the administration of certain drugs which have the power of preventing the formation of bacteria in the bladder. Acute cystitis is best treated by rest in bed. Free catharsis should be established in every instance, and the patient should have one or more watery movements of the bowels during each twenty-four hours. This is best accomplished by the administration of sulphate of magnesia every second or third day. If pain (tenesmus) is severe a narcotic is indicated. Morphin is especially useful if there is loss of sleep. A method that I have used with good results when pain on urination is severe is to instill a few drops of a four-per-cent. solution of cocain, and after a few minutes from ten to fifteen drops of a six-per-cent. nitrate of silver solution. Another procedure from which I have seen good results is the use of rectal irrigation of hot water for ten to fifteen minutes, followed by a hot enema of 25 to 30 drops of tincture of opium in four to six ounces of warm starch water. Suppositories of opium are useful in allaying pain. One that I am very fond of, and from which I have had good results, is the following:

Ext. hyocyami	gr. i
Camphoræ monobrom. . . .	gr. ii
Morphin sulphat.	gr. ss
Cocoa butter	q. s.

The diet should be bland; during the acute stage nothing but milk and Vichy, 4 ounces of each being administered every two hours. Of drugs there is a long list to choose from. I have used many of them and none has given me such good results as has been derived from the use of urotropin in 5 grain capsules, four times daily.

We are advised never to wash out the bladder during an acute attack of cystitis. This is good advice, as long as the urine remains bland and the bladder is emptied at each act of urination. But the urine should be watched and as soon as it presents any evidence of undergoing decomposition irrigation should be begun at once. For this purpose a warm two-per-cent. solution (100° to 105° F.) of boric acid or ichthyol may be used to good advantage. One of the best formulæ for irrigation is that introduced by Lobingier,[1] *viz.*:

Acidi borici	3 i
Borax	gr. xxx
Sodium chlorid	gr. xv
Aquæ	Oii.

Warm to 100° or 105° F. The irrigation can be performed through a double-current catheter or a meatus nozzle, after the method suggested by Janet of Paris. The latter method is by far the best and is aseptic.

In the treatment of chronic cystitis active inter-

[1] Medical News, October 15, 1892, p. 425.

ference is always necessary, and even then a permanent cure cannot be assured. To-day the disease is generally treated under four different heads, *viz.:* first, by medicines; second, by irrigations; third, by direct topical treatment, and fourth, by surgical interference. The treatment of chronic cystitis by drugs with an idea of producing a cure is fallacious. That certain drugs do exert a beneficial influence over some of the symptoms cannot be denied, and it is wise to administer a drug that answers the requirements the best in each individual case. Many different drugs are advised; some act well in some cases, while in others no appreciable diminution of the symptoms have been observed. In 1895 Nicolaier[1] called the attention of the profession to urotropin as a drug to be used in the treatment of urinary affections, and especially its property of preventing fermentation of the urine and the development of bacteria. In my opinion it is the best and safest drug that we have at our command. I have been using it during the past three years, and I have yet to find a case in which any disagreeable after effects were observed. As a urinary antiseptic it is superior to any other drug that I know of. The dose is from 3 to 7 grains four times a day. Urotropin has no direct effect on any existing lesion or inflammation; it simply renders the urine aseptic, and is thus a valuable aid in conjunction with other local treatment, except in cases of plain bacteriuria and ammoniacal decomposition without any inflammation of the mucous membrane of the bladder. In such cases it is a specific.

Irrigation of the bladder in chronic cystitis is recognized as one of the best methods of treatment at our command. The only method that should be followed is that of irrigation through the meatus by the meatus-nozzle, as suggested by Janet of Paris. The strictest aseptic precautions must be observed, such as cleansing the glans penis, the meatus, the urethra, and especially the instrument used, as well as the hands. Irrigation may be practised by allowing a small quantity of the irrigating fluid to run into the bladder and then have the patient void it, or better, allow a sufficient amount to run in until the bladder is moderately distended or until the sensation of a full bladder is conveyed to the patient. This latter procedure is the best as the entire mucous surface of the bladder is thus thoroughly cleansed.

When there is much pus and mucus present in the urine it will be well to use a one-sixteenth-per-cent. solution of salicylic acid as recommended by Bryson.[2] With the same end in view a 1-per-cent. solution of nitrate of silver, bichlorid of mercury, 1 to 50,000 or 1 to 60,000, or a 1½-per-cent. solution of carbolic acid may be used, but none of these is so pronounced or lasting as the solution of salicylic acid.

In commencing with this form of treatment it is best to give two treatments a day, one in the morning, the other in the evening. At the morning séance it is best to employ one of the stronger solutions, and a milder solution, such as the one suggested by Lobinger or Thompson, at the evening treatment. After the most distressing symptoms have disappeared, if the urine remains alkaline, with a tendency to throw down phosphates, Harrison[1] recommends the use of 5 grains of citric acid to the pint of warm water. When the urine remains purulent Nunn[2] advises the use of quinin, 1 grain to the ounce of water, to which should be added 1 drop of nitric acid. In these cases I have used a 1-per-cent. solution of ichthyol with a good deal of benefit.

At the first blush it may appear that this method of treatment is fraught with danger to the ureters and kidneys. In my experience I have never observed any symptom that would point to this complication, and I believe that it is next to impossible to force fluid into the ureters or kidneys by irrigating the bladder from the meatus. I have experimented in the way suggested by Lewin and Goldschmidt,[3] and by Guyon and Courtade,[4] and never once have I been able to force the fluid into the ureters or kidneys from the meatus through the bladder.

The practice of instilling medicine into the bladder in the treatment of cystitis was introduced by Guyon of Paris who is a great advocate of this method of treatment. The solutions that are most used are nitrate of silver in the strength of from 1 to 15 per cent., and corrosive sublimate in the strength of 1 to 10,000 to 1 to 2000, from 15 to 60 drops being instilled at one sitting. The amount introduced is allowed to remain in the bladder from 15 to 30 minutes, when it is washed out with a mild antiseptic fluid. I have found that iodoform in sterilized oil is very efficient in the strength of 5 to 10 per cent. This method is especially recommended by Guyon for the treatment of tuberculosis of the bladder.

Surgeons for San Francisco.—On July 5th the War Department ordered eleven additional surgeons to report to General Shafter for duty in the new general hospital at the model camp in San Francisco.

CLINICAL MEMORANDUM.

A CASE OF PLACENTA PREVIA.[1]

BY CHARLES A. HELVIE, M.D.,
OF CRETE, NEB.

C. Q., aged twenty-two years, English, housewife, married, entered the maternity of the Erie County Hospital, Buffalo, N. Y., July 20, 1895, at 4.30 P.M.

Personal History.—She had never had any sickness. Menstruation always regular, four-weekly type. She was slight in figure and appeared anemic.

Family history.—Mother died of "brain fever."

Physical Examination on Admission.—Inspection: no abnormalities. Palpation: Foot presentation with head to left. Position transverse with dorsum in fundus.

Auscultation.—Fetal heart heard above umbilicus; frequency 160; regular.

Vaginal Examination.—Vagina roomy. Cervix effaced. No dilatation.

Mensuration.—Height above pubes of navel 13 cm., of fundus uteri 19 cm. Distance from ensiform to fundus 4 cm. Distance between spines, 22 cm. Between crests 26 cm. Conjugates, extremes 19 cm.

Urine.—No specimen obtained before labor began.

Labor.—Pains began at 7.30 P.M., three hours after admission.

First Examination after Beginning of Labor.—8.45 P.M. Dilatation complete. Bag of water intact and near vaginal orifice. Pains fair.

Second Examination.—10.00 P.M. Foot found presenting to anterior and nearly a finger's length from vaginal orifice. Pains same as before.

Third Examination.—11.15 P.M. Bag of water still intact but near vaginal orifice. Presenting foot half a finger's length in. Pains almost ceased for a time.

Fourth Examination.—12.30 A.M. Membranes intact. Fetal heart sounds not heard. No fetal movement detected.

There had been some hemorrhage all along, so that the napkins had to be changed frequently. After the third examination (11.15 P.M.) the hemorrhage increased markedly. During the examinations the patient always complained of pain, so that they could not be made as thorough as they should have been. At 1.00 A.M. it was decided to anesthetize the patient in order to make a more complete examination. Chloroform was used. The case was now found to be one of placenta previa. The placenta was high enough up to be beyond the reach of the examining fingers, until after the anesthetic was given. The edge of the placenta was then felt to the right, anteriorly. The membranes were ruptured artificially and rapid delivery begun. When the membranes were ruptured the cord was found to be prolapsed. Delivery was effected by traction on the feet and legs.

Birth at 1.30 A. M. Child was still-born, but vigorous efforts were made to resuscitate it. These were partially successful. The child died two hours after birth. It was well formed. Its weight was 3 lb. 11 oz. While I was working with the child, my colleague, Dr. Robinson, took charge of the mother.

Placenta expressed (Credé) at 1.32 A.M. Ergot, gtt. xxv, by hypodermic injection was then administered to the patient. The weight of the placenta was 10½ oz. It was of an oval shape, thin and soft. One edge was very dark colored and contained a blood-clot which occupied about one-fourth of the placenta. The surface was studded with white infarcts.

The cord was 65 cm. in length. Its insertion was marginal. It was small near the placental end and gradually enlarged toward the fetal end. Near the fetal extremity it was distorted by large venous dilatations and near the middle there was quite a large nodule of Wharton's jelly.

Immediately after delivery the patient went into collapse. Her head was quickly lowered, hot water-bottles were placed about her and vigorous massage of the extremities and uterus was kept up. Hypodermic injections of brandy were given about every fifteen minutes until five doses had been given. Strychnin sulphate, $\frac{1}{30}$ of a grain was also given hypodermically once every hour until three doses had been given. Inhalations of amyl nitrite were given at first, and later oxygen was administered until four gallons had been used. Several high enemas of hot salt solution were given and one enema of hot strong coffee. It was three hours from the time the collapse set in before the patient began to rally. At the end of this time the uterus began to show signs of contracting under the massage, and the patient complained of pain and nausea. A vaginal douche of hot mercuric bichlorid, 1 to 5000, was then given and the binder put on.

Her temperature at 8.45 P.M. was 99°, at 12.45 A.M., 98° and three and half hours after delivery 97.5° F. The pulse at this time was 120.

About eight hours after delivery the patient became restless, complained of pain in the abdomen and began to vomit. The vomiting continued for about thirty-six hours. Nothing seemed to relieve it. During this time hot milk ℥ viii was given per rectum, every six hours. The pain in the abdomen was relieved only by permitting the patient to lie upon her right side.

During the first twenty-four hours a small amount of urine was passed but urination was always accompanied by a bowel movement. Thus what urine was passed was so mixed with fecal matter that it could not be examined. At the end of the first twenty-four hours the patient was catheterized but no urine obtained. It was not until the fourth day that a specimen for examination could be obtained. This was by catheter and amounted only to ℥ iii. It was acid in reaction. The specific gravity was not obtained. The heat and nitric-acid test showed it to be almost solid with albumin. Urea, by the Doremus test, was .03. By the microscope there was shown epithelium, pus, bacteria, and urates. No casts were found.

The patient's condition became gradually worse and death ensued on the fifth day. During the last twenty-four hours she became comatose. Her breathing became stertorous and of the Cheyne-Stokes type. The skin became dry and harsh and minute crystals of urea

[1] Read before the Nebraska State Medical Society.

could be seen glistening upon it. With this condition there was present a very peculiar odor.

The cause of death was uremia consequent upon nephritis with almost complete suppression of urine. Whether this nephritis was ante-partum or acute post-partum it is not possible to say positively since no autopsy was made and there was no examination of the urine before labor set in. The previous anemic condition of the patient, together with the hemorrhage during labor, were factors which contributed largely to the disastrous result. The chloroform anesthesia may have been another factor of considerable importance.

I have said nothing of the treatment pursued in the case after the first signs of uremia. In passing I will state that the usual recognized methods of treatment were followed: hot baths and hot packs, hypodermic medication to sustain the strength and induce perspiration, and finally intravenous injections of normal salt solution.

What would have been the result in this case if the labor had been conducted differently? The question hinges upon a point in obstetrical teaching—spontaneous rupture of the membranes or their artificial rupture, early or late. For the most part I received my obstetrical training under the "immortal" Jaggard. One of his dogmas was that the bag of membranes, being a natural dilator not only of the os uteri but of the whole parturient canal, should be left alone and allowed to rupture spontaneously, unless there were some very positive indications for interference. Just here it may be urged that those indications were present in the continued hemorrhage. In reply to this it can be said that the hemorrhage, although continuous, was only slight, not so much as often accompanies the slight lacerations of the cervix in process of dilatation. There was no history of hemorrhages before labor. On account of the hypersensitive condition of the parturient canal and the apparent high position of the placenta the true state of affairs could not be determined until after complete anesthesia. It was not until then that the case was determined to be one of placenta previa.

One of my colleagues in the hospital, Dr. Mord, in accordance with the training that he had received, practised the rupture of the membranes as soon as the cervix was completely dilated. In this case, it has seemed to me, that if I had ruptured the membranes at 8.45 P.M., at the time when dilatation was found to be complete and only one hour after the beginning of labor, the final result would have been quite different; both mother and child might have been saved. The child probably would not have been asphyxiated. There would have been saved to the mother at least four hours when her strength was slowly ebbing away, while the subsequent uremia might have been averted.

I report this case not alone because of the extreme interest that it has had for me, but that it may serve to warn others to be on their guard for even the slightest danger signal.

I am well aware of the fact that the conduct of the case may be severely criticised. It was partially with the purpose of eliciting this criticism that I have presented it somewhat in detail.

MEDICAL PROGRESS.

Maternal Impressions.—OGLE (*Charlotte Med. Jour.*, May, 1899) and LANDAU (*Monats. f. Geburts. u. Gynäk.*, May, 1899) discuss the philosophy of this puzzling subject. Both cite numerous well-authenticated instances in which the birthmark or deformity of the child suggests more or less some fright or accident which occurred to the mother during her pregnancy. Both admit that it is difficult to explain the very widespread belief in maternal impressions which has existed from the earliest times in every country. Ogle says that it is hard to imagine how a mental impression of the mother can affect the development of a portion of the child, in the absence of any direct nerve connection between the two, but he apparently hesitates to set down as pure superstition or error of observation all the recorded cases of maternal impressions from Aristotle to the present time. Landau is more outspoken, for in the closing words of his article, he says, "I admit that it is striking that earnest thinkers of great power of observation, wide learning, and sharp intellect, bring forward certain cases which seem to uphold the primitive belief. Still, great men have made mistakes before now. Maternal impression is and remains a superstition, and despite Welsenburg's highly instructive work on the subject it has not become worthy of scientific recognition."

Radical Cure of "Slipped" Herniæ of the Large Intestine.—FROELICH (*Gaz. Heb. de Med. et de Chir.*, April 25, 1899) discusses the radical cure of those herniæ of the large intestine, either cecal or sigmoidal, which have "slipped" down behind the peritoneum, and are therefore partially or wholly without a peritoneal sac. This condition has been most perplexing to surgeons, and most operations on strangulated herniæ of this type have been followed by the death of the patient, while the operations done for radical cure when no strangulation existed, have been unsuccessful in curing the hernia. The author reports three such cases, in two of which attempts to separate the intestine together with the sac, from the tissues about the ring, in order to reduce the hernia *en masse*, were followed by fecal fistulæ. All three patients recovered, but without cure of the hernia. From a study of these and twenty-one published cases, Froelich concludes that in irreducible inguinal hernia one ought always to keep these "slipped" hernia in mind. The diagnostic points are the presence of fecal lumps, distention when gas is pumped into the rectum, a drawing feeling at stool, and often a diminution in the size of the hernia after evacuation of the bowels, and an irreducible hernia from the beginning. In regard to the treatment, it is advised to dissect sac and intestine posteriorly with the fingers high enough up to permit of the easy closure of the ring. Failing in this, the intestine should be resected. Even then one must not expect to obtain a radical cure, but the condition ought to be such that the hernia can be held in place by a truss. In strangulated herniæ of this type, the surgeon should remember that there may be loops of small intestine which

are also strangulated, and which must be freed and reduced if recovery is to be secured.

Error of Sex as a Ground for Divorce. — Neugebauer (*Centralbl. f. Gynäk.*, May 6, 1899) has collected reports of no less than fifty cases in which divorce has been granted on account of an error in the sex of one of the contracting parties. It seems incredible that such a mistake should occur so often, but the conformation of the genitals of some of these hermaphrodites was such as to deceive medical men who could not in some instances agree upon the sex of the individual, even after an examination. One remarkable case is recorded in which a male hermaphrodite had successively three husbands, and it was only after she, or rather he, had given a venereal disease to the third husband that the latter applied for a divorce. In forty-six out of the fifty recorded cases a man had married a male hermaphrodite. In one case the sex of the parties is not given, and in three instances women married female hermaphrodites. In one of these instances the supposed husband later became pregnant, and was delivered of a full-term child. There are numerous instances in which a matrimonial engagement has been broken on account of the discovery that the parties to the agreement were of the same sex.

Repeated Cæsarian Section. — Pollak (*Centralbl. f. Gynäk.*, April 15, 1899) looked up the literature of Cæsarian section and found that it had been performed a second time upon the same patient no less than thirty times. A still more remarkable fact is that in twelve cases it has been performed three times upon the same patient, the operation being twice concluded by the removal of the uterus. Four women have had Cæsarian section performed upon them four successive times, while one, a patient of Birnbaum, was five times subjected to this operation, this unique series of deliveries being terminated unfortunately by the death of the mother from pulmonary embolism. Pollak adds the details of a case in which Cæsarian section was three times performed. The last operation was done by himself, and a careful examination of the uterus showed that its wall at the sites of the previous incisions was as solid and as thick as at other places.

In this connection may be mentioned a case reported by Pryor in which Cæsarian section was successfully performed upon a woman whose abdomen had been opened five years previously for the removal of a large fibroid. At the time the uterus was opened, another fibroid was present, but it was decided not to remove the tumor. It grew so rapidly, however, that laparotomy had to be performed within three months, at which time the whole uterus was successfully removed.

THERAPEUTIC NOTES.

Treatment of Acute Rheumatism Prophylactic of Pericarditis.—Delearde (*La Presse Med.*, April 29, 1899) says that no other drug is so good as salicylate of soda to prevent pericarditic sequelæ after acute articular rheumatism. Three rules are to be observed, *viz.*, to give large initial doses of the salicylate, to give it at short intervals on account of its rapid elimination, and to keep up its administration for at least ten days after the disappearance of all pain. To adults he gives from 90 to 120 grains a day in the beginning of the attack, in divided doses, every three or four hours. After the disappearance of acute symptoms the dose is reduced so that the patient gets only 45 to 60 grains a day. The medicine is given either in capsules or in such a mixture as the following:

℞	Sodii salicylatis	ʒ jss
	Spiritus vini rectificati . . .	ʒ ijss
	Syr. ribis	ʒ x
	Aquæ destillatæ . . .	q. s. ad ℥ iij.

M. Sig. Take the whole in doses of a tablespoonful during the twenty-four hours.

Treatment of Impetigo Contagiosa.—The crusts are to be removed by repeated washings with warm water and soap (Stelwagon, "Keating's Cyclopedia," vol. v.) and an ointment of ammoniated mercury of the strength of from 10 to 20 grains to the ounce. In cases in which the itching is severe a lotion composed of a saturated solution of boric acid, containing ½ a dram of carbolic acid or resorcin to the pint, should be applied. This prevents innoculation of new points.

Treatment of Acute Dysentery.—Sodré ("Twentieth Century," vol. xvi) recommends in lieu of the large doses of infusion of ipecac often given the following:

℞	Pulv. ipecac.	gr. iss
	Pulv. opii	gr. ⅓
	Calomel	gr. ¾.

To be given in a capsule every two hours, or administer about fifteen minutes before the first dose of ipecac, 12 drops of a mixture containing menthol (gr. iii), tinct. opii (gr. ss), and Jamaica rum (ʒ v), and apply a mustard plaster to the epigastrium. If the ipecac is not tolerated saline cathartics should be given in small doses, often in alternation with the ipecac. The salines—sulphates of sodium or magnesium in doses of about 2 drams—are indicated when there is constipation, or small evacuations with much colic and tenesmus. Astringents—opium, bismuth, and salol—are useful, but must be given cautiously and alternated with the saline cathartics. Ulceration in the rectum and colon is to be treated by enemata, containing opium and bismuth. The following plan of treatment is very often satisfactory: Sulphate of soda (or magnesia) is given on the first day of the disease, and on the second, third, and fourth days, every three hours, a capsule containing:

	Magnesia	gr. iv
	Bismuth subnitrate . . .	gr. vi
	Pulv. ipecac	gr. i
	Pulv. opii	gr. ⅓.

For Acute Diarrhea.—

℞	Sodii bicarbonatis	ʒ i
	Spts. ammonii arom. . . .	ʒ iii
	Tinct. cardamomi comp. . . .	ʒ vi
	Aq. cinnamomi . .	q. s. ad. ℥ vi.

M. Sig. Two tablespoonfuls every two or three hours.—*Yeo.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

THE TREATMENT OF SUMMER DIARRHEA IN INFANTS.

WE are glad to be able to present to our readers, just at the time when its very practical points may be of most service to them, Dr. Chapin's paper on this timely subject, with a detailed report of the discussion that followed it at the New York Academy of Medicine at its last meeting of the season. There is nothing that is absolutely new to be said on the subject, but the emphasis laid on certain points in the course of the discussion shows that physicians who have a very large experience in children's diseases are now definitely agreed as to the advisability of certain measures that have been more or less in doubt though every year growing more and more into the practice of the profession.

The theory that children should not be given carbohydrates because they secrete no diastasic ferment to digest them is now definitely abandoned and two distinct advantages are claimed for the mixture of carbohydrates with baby's milk. First, there is the mechanical separation of the particles of the coagulated milk which prevents its coagulation in thick solid masses incapable of penetration and digestion by the stomach juices; and second, certain antiputrefactive action is claimed for carbohydrates. Their fermentation which used to be so much dreaded or at least railed about, it is now urged, causes the liberation of free acids and these prevent the growth of intestinal bacteria which especially luxuriate in an alkaline medium. When cow's milk is used, then, in the feeding of infants in the summer time especially, its dilution with barley-water or some other cereal solution is considered much more to be preferred to its dilution with plain water.

As to treatment all the specialists in children's diseases insist on the stoppage of all feeding just as soon as diarrhea asserts itself in the hot weather. There is great danger in delaying the institution of this radical measure while an over-anxiety that would stop the administration of milk, and so perhaps anticipate the necessity for absolute gastro-intestinal rest by a few hours, can do very little if any harm. A single attack of vomiting in a child whose stools are more frequent and watery than normal must be the signal for the withdrawal of all milk from the dietary if the physician would not neglect his plain duty as outlined by the best recent experience.

As to drugs, not much can be said. All authorities are agreed that opium must not be used, in the hope to control by its help the number of stools. It must never form part of the diarrhea mixture itself of which the main ingredient should be one of the salts of bismuth; it must not be administered until after stomach and intestines have been relieved by purgation, lavage, and high injections of any toxic material that is present. It must be employed only when there are direct indications for it, *i. e.*, only when there is exhausting restlessness or tenesmus and pain. For the restlessness it has been pointed out that hydrotherapy forms an excellent substitute for opium and one that carries with it none of the dangers of the rather treacherous drug. Whenever the temperature of the little patient is above 102.5° F. for any length of time it should be placed in a bath somewhat above 90°, which should be rapidly lowered to about 80°, not lower. As a rule not more than a very few minutes will be necessary, but the bath may be continued for ten minutes, a cold cloth

being kept on the child's head. For tenesmus the local use of opium per rectum is most advisable, 2 or 3 drops of the tincture in a tablespoonful of starch water relieving the pain, decreasing the fruitless efforts at stool, and avoiding most of the deleterious effects of the drug on the general system.

Abroad, of very late years a good deal has been said of the value of tannigen in controlling the stools. Dr. Blackader of Montreal, in the March number of "Progressive Medicine" in an excellent review of the recent literature on summer diarrheas, quotes no less an authority than Escherich, the well-known Professor of Children's Diseases at the University of Graz in Austria, who speaks very favorably of tannigen and claims for it a distinct disinfectant and bactericidal effect. Kraus and Biedert have also written in its praise, especially for chronic intestinal catarrh. It is a tasteless powder, therefore easily administered and is given in doses of 2 to 5 grains four times a day. It is especially useful in cases of follicular enteritis, where local measures are of little avail. Its administration is continued in lessened doses after the acute symptoms have subsided and it is said to hasten convalescence, which is often apt to be tedious.

Stimulants used early in the case, though sparingly until marked signs of prostration assert themselves, are growing in favor. Recent reliable physiological observations, notably Atwater's work, seem to confirm an old view with regard to alcohol, that it is oxidized in the body and does replace food material to a very appreciable extent. When all milk feeding is stopped it undoubtedly serves to keep up the child's strength. Bouillon has been recommended for the same purpose. Meat-products generally, while acting as effective nutrients do not seem to furnish the favorable culture-medium for micro-organisms that milk does.

For the severe states of depression that develop in the serious cases of diarrhea the subcutaneous injection of normal salt solution has sometimes given excellent results. Very often these cases are hopeless. The paralysis of cellular activity has been too great to permit reaction. The normal salt solution seems, however, in many cases to dilute the toxins in the circulation and arouse conservative processes that make for resistive vitality. In an infant an ounce of the solution may be injected into the thigh or back by means of a hypodermic needle or an ordinary Davidson syringe and will often be followed by a most favorable reaction. The injections may be repeated about three times a day. Even in what seems hopeless collapse the effect is often according to French writers almost marvelous.

RECENT EPIDEMICS OF CEREBROSPINAL MENINGITIS.

There is still much to be learned about epidemic cerebrospinal meningitis, and Europe looks to America for this information, as the disease is rarer in the Old World than in the new. Class, a member of the Health Department of Chicago, made a special study of the cases occurring in the recent epidemic in that city, and gives in the *Journal of the American Medical Association*, a summary of the histories of thirty-eight patients. The mortality of these patients was 65 per cent.; but he believes that a complete record of all the cases which occurred in the city during the epidemic would show a much lower mortality, since the thirty-eight reported by him were chiefly those of hospital practice.

Since those in attendance upon the sick almost never take the disease, and since an epidemic does not spread by contiguity as does smallpox or yellow fever for instance, the contagiousness of the disease has been generally denied. There are, however, instances in which several members of one household are victims, a number of such being seen in the Chicago epidemic, and the majority of all the cases occurred in a territory of about one square mile. Class believes that the disease is contagious like phthisis, which would explain its spread geographically in congested districts inhabited by persons of careless habits, and the lack of a similar spread among the intelligent and well-to-do. Several pathologists have shown that the germ exists in the buccal and nasal mucus. As the germ is short-lived, it is easily understood why a family moving into rooms previously occupied by a patient, probably would not contract the disease. An examination of the dwellings inhabited by those who fell ill during this epidemic showed that many of them were in a very bad sanitary condition. The records of previous epidemics in other places are in accord with this statement. Hence, Class advocates the isolation of patients and the disinfection of their

evacuations, the correction of sanitary defects, and the notification of the sanitary authorities. Nothing new was brought out in the way of treatment. The writer mentions that difficulty in swallowing was observed in six cases each of which terminated fatally.

Two other recent epidemics of this disease are reported. One was in the vicinity of Morganstown, Kentucky, where fourteen patients, almost all of them males, died in from one to eleven days, (only two lived more than three days) while two were in critical condition at the time of report, and three or four others had recovered after a slight illness, the diagnosis of meningits in their case being doubtful. The other epidemic was in the vicinity of Henderson, Kentucky. Quinn, who reports the latter, estimated that one hundred persons were attacked, of whom about seventy-five died. In the midst of this epidemic, not a doctor or nurse suffered; but in adjoining counties where there were only a few cases, two doctors lost their lives from the disease.

NEW INSTRUMENTS AND THE "DICHOTOMOUS" METHOD IN MEDICAL ADVERTISING.

A DISTINGUISHED French surgeon, not long deceased, is said to have owed not a little of the very large and lucrative practice that he enjoyed to his uncompromising belief in the practical application of the botanical principle of dichotomy, equal division, in the matter of consultation cases. His facetious countrymen have taken the word which is applied by botanists to plants that multiply by division and applied it to medical men whose monetary accretions follow a similar law. They call them dichotomous, and have thereby enriched medical literature and language with a very expressive term.

It is not unusual to have this system of "divvying up" referred to abroad as typically American. That it is not exclusively so the little legend we have just related and the very apt appropriate term the French have invented for what is evidently not an isolated incident, seem to show. A circular that has been going the rounds of doctors' offices here in New York, and very probably elsewhere in the country, indicates that there are other countries in Europe outside of France where the principle of division of the spoils is not unknown. At least it is scarcely to be supposed that the very promising system of division suggested in the circular sprang fully panoplied for the American campaign from the fertile brain of the American agents.

The circular in question which smacks somewhat of its foreign origin in the construction of its phrases offers to physicians a goodly share of the spoils ($25 to $50) for every patient that on the physician's recommendation adopts the company's inventions for the removal of impotence. These inventions have the approval of high authorities abroad (names given), and cost $150 to $200. There have been grave doubts expressed abroad as to the advisability of the use of such methods, except in selected cases under extraordinary circumstances, but with that we are not concerned. The method adopted for introducing the instruments deserves the severest censure and should keep physicians, who value their reputations for honorable dealing with their patients, from advising them until such methods are abandoned.

Manufacturers and agents must be taught the lesson that what is gained by these objectionable advertising methods with certain classes of the profession injure them so much with the great body of self-respecting medical men that their use does not pay in the end. Only this practical commercial argument will reach such people. The methods in question are unfortunately becoming contagious in various trades connected with medicine, and this last extravagant manifestation should receive a severe rebuke.

MEDICAL MATTERS IN NEW YORK.

OPTICIANS AND PHYSICIANS—A ROBBER OF DOCTORS' OFFICES CAUGHT—ST. JOHN'S GUILD — FATAL ERROR IN DIAGNOSIS—THE HIGH-PRESSURE SYSTEM IN NEW YORK SCHOOLS—TENEMENT-HOUSE REFORM—YELLOW FEVER IN NEW YORK HARBOR.

THE New York State Optical Society, at its meeting at the Fifth Avenue Hotel on June 27th, adopted a resolution deploring the action of certain medical societies of other States in endeavoring to disrupt the hitherto cordial relations which have existed between physicians and opticians.

In arresting one George Freeman the Brooklyn police seem to have caught an old offender, whose particular "lay" has been to call and ask for "the doctor" in his absence, be received in the waiting-room, and then to quickly disappear a few minutes after being left alone with whatever property he could conveniently carry off. On one occasion Freeman was seen by the doctor's

servant to leave the house with a bundle. She ran after him, and accused him of theft. He then handed her two coats and an umbrella belonging to her employer, said he had made a mistake, and hurried away.

The "Helen C. Juilliard," the new floating hospital of St. John's Guild, made its initial trip on July 6th. This boat has accommodation for 1900 persons. Her most conspicuous feature from a hygienic point of view is the bath-rooms, in which forty-one people can take salt-water spray baths simultaneously. Patients who are found to need longer treatment than can be given in a day's outing on the boat are carried to the Seaside Hospital of the Guild, at New Dorp, Staten Island. This establishment is governed by a board of ten New York and two resident physicians.

A few days since a man was stabbed in the abdomen during a quarrel. His assailant had used a pocket-knife. The wounded man went to a hospital near by, where his wound was examined. The surgeon considered it only a superficial wound, dressed it, and sent the man home. That night symptoms of peritonitis developed, and next day the wounded man was taken to Bellevue, where it was discovered that the abdomen had been penetrated. The man died.

Dr. W. Gill Wylie, chairman of the Medical Board of the Board of Education, has begun an agitation for a reform of the present school system as it applies to girls. He considers that girls between the ages of eleven and sixteen are required to do too much work. A point gained thus far is that the age now fixed for admission to the Normal School is fifteen, instead of fourteen, as it used to be. Dr. Wylie says: "The danger resulting from the amount of study required at present is not to the life of the girl, but, coming as it does in the formative period of a girl's life, the evil effects are bound to be manifest in her children."

The tenement-house committee of the Charity Organization Society has prepared a series of ordinances relating to tenement-house construction, and has presented them, in a report, to the Municipal Building Commission. It was observed that New York City's tenements are a disgrace to the city and the State, that dangerous and unsanitary conditions are allowed to prevail in them, and that these conditions are growing steadily worse year by year. One of the suggested ordinances is aimed at the dark, narrow, and unventilated air-shaft, and the resulting dark, damp, and unventilated rooms that open upon it, and provides that the shafts shall not be less than six feet wide in any part and have not less than 150 square feet in superficial area. Other provisions are that no tenement shall be more than six stories high, that living rooms shall each have 600 cubic feet of air space, that there shall be at least one bath-room for every twenty families in every tenement, and that the walls of tenements shall be carried three and one-half feet above the roof, so that the roof may be used as a playground.

The Government Transport "McClellan" from Santiago, Cuba, arrived at quarantine, July 6th, with two well-developed cases of yellow fever and two suspicious cases on board. The suspects did not develop the disease, and have been discharged. One of the persons in whom the disease developed was Miss L. C. Clendenin, daughter of Surgeon-Major Clendenin, who died of yellow fever at Santiago the day following the departure of the "McClellan." The attack is mild in her case and she is being cared for at the quarantine hospital. The other case proved more serious and the patient submitted to treatment with the serum developed by Dr. Doty, Health Officer of the port. This serum is produced from the Sanarelli bacillus by injecting cultures directly into the veins of a horse. By this process Dr. Doty believes that a stronger antitoxin is developed than by the subcutaneous method. He has despatched Dr. Bernard E. Baker of Charleston, South Carolina, with a supply of serum to Vera Cruz, Mexico, to give the remedy a prompt and thorough test. The epidemic of yellow fever which is raging there will enable him to use it in the early stage of the disease when it should be the most efficacious. To Mr. Lackey, the patient in the quarantine hospital, a subcutaneous injection of the serum was given at eleven o'clock, two o'clock, and seven o'clock. During this time the patient's temperature fell two degrees and his general symptoms improved.

ECHOES AND NEWS.

Vienna Losing Its Lead as a Medical Center.—In the winter semester there were 1382 medical matriculants at Vienna, 1341 at Munich, and 1311 at Berlin. Wurzburg stands next in the list with 713, while the once popular Heidelberg had only 240.

A Beer Tablet.—The latest reported German invention is a "beer tablet." The beverage is dried and compressed, and when water is added to the tablet, carbonic acid gas is formed, so that a foaming beaker is produced, as good, it is said, as if it were freshly drawn from the barrel. It is non-alcoholic of course.

A Congress of Deaf-Mutes.—A committee of the leading deaf-mutes of Paris is making arrangements for an international congress at the Exposition in 1900 and has asked the four following Americans to act as a sub-committee: The Rev. A. W. Mann of the Central Western Deaf-Mute Mission of Gambier, Ohio, the Rev. J. M. Koehler, rector of All Soul's Church, Philadelphia, Professor T. F. Fox of the Fanwood Institution, Washington Heights, and E. A. Hodson, editor of *The Deaf-Mutes' Journal.*

Medicine's New Field.—Professor Charles Sedgwick Minot of the Harvard Medical School delivered the annual address to the Yale Medical seniors on June 27th. He said: "We are brought to the conclusion that though the primary functions of our medical schools is to educate practitioners of medicine, yet they ought to assume now the further and higher function of training medical investigators. The requirements of comparative medicine call for more changes than we have yet mentioned. The very word comparative implies that animals shall be included in the study."

Koplik's Spots in Prague.—Dr. Ludwig Knospel, the assistant of Professor Ganghofner in the clinic for children's diseases at the German University of Prague, has followed carefully all the numerous cases of measles that came to the clinic and has found Koplik's spots of the greatest value for the early diagnosis of the disease. He reports that he has noticed the red spots with bluish-white punctations on the mucous membrane of the cheeks and lips from three to five days before the appearance of the usual eruptions of measles. (*Schmidt's Jahrbucher* for June, from the *Prager Medicinische Wochenschrift.*)

Decreased Death-Rate.—The mortality bulletin of the New York State Board of Health for the month of May says that the number of deaths reported was 9556, or just the average for the ten years past. It is 200 less than that of May, 1898, and 850 less than that of the preceding month, the average daily mortality having been reduced from 346 to 308. For the preceding four months the average daily mortality was 370. The death-rate is reduced from 17.75 to 16.00. The decrease from last month is in acute respiratory diseases, from which there were 500 fewer deaths, and other local diseases caused 300 fewer deaths.

Report of Plague at Paris Denied.—The rumors that there have been deaths from the plague in Paris have been so persistently circulated that the matter was brought before the Academy of Medicine for investigation. The Academy has determined that the rumors were absolutely without foundation, other than an anonymous letter written to an official of the goverment, stating that five employees of the large department-store, Bon Marché, had died from plague contracted from handling rugs. The police at once took the matter up, and ascertained that there had been no deaths among the employees nor any cases of severe illness. The sanitary conditions in the store were found to be as nearly perfect as possible.

The Progress of the Plague.—Reports from Japan announce that the plague still remains limited to the island of Formosa. At Bombay, Calcutta, and other towns in the Bombay Presidency, the disease seems to be declining. At Alexandria, Egypt, the total number of cases occurring previous to June 16th was thirty-two, with ten deaths. Eight of these were of Europeans. A quarantine of six-days' detention has been declared at Naples on all ships having touched at Egyptian ports, and the importation of goods from all infected countries has been practically stopped. Turkey has established a ten-days' quarantine against vessels from Egyptian ports, Greece eleven-days' quarantine, and Malta two-day's quarantine. No further news has been received regarding the appearance of the plague at San Francisco.

Epidemic of Diphtheria in the State Hospital for the Insane at Willard.—Diphtheria was reported July 5th as epidemic among the 2300 patients and 600 employees at the State Hospital for the Insane at Willard, near Geneva, N. Y. The hospital has been placed under a rigid quarantine. There are now seventeen cases at the institution. It first appeared at the institution about a month ago, but the patients were quickly isolated. They recovered, and it was believed the disease had been stamped out. There was a further outbreak last week, and it is this which has alarmed the authorities. The disease is of a very mild type, and attacks the younger persons. Of the seventeen now under treatment fourteen are employees. The disease is being kept under control by the free use of antitoxin and no deaths have thus far been reported.

The Study of Cancer at the Buffalo Laboratory.—The careful investigations into the etiology of cancer being carried on at the State expense at the Buffalo (New York) Laboratory are attracting attention abroad. It is reported that the British Cancer Society of London has appointed Dr. A. L. E. Duffy to investigate the work being done at Buffalo and collect data bearing upon the spread of the disease in the United States. As intimated by Dr. Roswell Park in his article published in the MEDICAL NEWS April 1, 1899, the investigations at the Buffalo Laboratory point strongly toward confirmation of the germ theory of the disease. On the other hand Dr. Lambert Lack of London has recently reiterated positively his belief, founded on late investigation, in the old theory that cancer is originally a local disease due to a specific injury to the basement membrane of mucous surfaces and allied structures. He also announces the discovery of a prophylactic and curative serum.

Experiments in the Eradication of Malaria.—Major Donald Ross, I.M.S., well known for his researches on the connection between the mosquito and malaria, will head a deputation of observers from the new tropical medicine department of University College, Liverpool, which will go to Sierra Leone in August. They will be in Africa during the period of greatest prevalence of malaria and when the conditions are most favorable for observations on the disease and especially as to the means by which it is spread. Major Ross considers that he will be able to demonstrate to the members of the expedition the truth of his theory that malaria is carried about by a certain species of mosquitoes and is directly caused by their bites. The special purpose of the expedition will be to determine what species of mosquitoes are malaria-bearers in a given region and then having found their haunts in swamps or ponds to cover them up and see if they will not be able to prevent in this way the further distribution of the disease. As this is the first practical attempt of this kind for the eradication of malaria, the outcome will be watched with great interest by the whole of the medical world.

The British Medical Association.—The sixty-seventh annual meeting will be held at Portsmouth August, 1, 2, 3, and 4, 1899. The president-elect is Dr. John Ward Cousins. The following are the subjects announced for discussion in the several sections: "The Medical Tests Required at Present for Admission to the Public Services," "The Prevention and Remedial Treatment of Tuberculosis." Surgery: "The Diagnosis and Treatment of

Gunshot Wounds of the Abdomen," "The Prevention and Treatment of Syphilis in the Navy and Army.' Obstetrics and Gynecology: "The Treatment of Fever Following Delivery, with Special Reference to Serumtherapy," "The Natural Menopause Compared with (*a*) the Menopause Produced by Removal of the Uterine Appendages, and, (*b*) the Menopause Produced by Removal of the Uterus without Removal of the Appendages." Tropical Diseases: "Psilosis or Sprue; Its Relations (Etiological and Pathological) to Other Forms of Tropical Diarrhea, and Its Treatment," "On Thermic Fever (so-called Siriasis), with Special Reference to Its Alleged Microbic Causation," "The Agency of Insects in Spreading Infections."

Yellow Fever in Cuba.—Since July 4th, the date of our last report, yellow fever has continued to claim its victims among the members of the various garrisons. At Santiago Surgeon-Major Clendenin has died of the disease, also Chief Commissary-Major Heatwole and Signal Officer McLaughlin. At Manzanillo two new cases were reported July 7th, and on the same date two deaths from the disease at Puerto Principe. At Santiago the troops have been placed in camps on the hills and are frequently moved; most careful hygienic and sanitary precautions have been instituted. Elevation seems to have little effect upon the disease. Regarding the appearance of yellow fever in the hills, General Brooke has telegraphed as follows to the War Department: "In 1868-1878 Board of Health, Santiago, reported yellow fever 1000 feet above sea-level; in Mexico, Cordova, 2962, at Las Aurinas, 3308. New Castle, Jamaica, 4200 feet, has been visited several times, and several places in Peruvian Andes, 4000 feet, have been afflicted with it. Everything is being done that can be to control the disease." Commenting on this fresh outbreak in Cuba, General Sternberg says that it was not unexpected by the War Department. "Cuba is an infected island and this is the yellow-fever period."

Medical Officers Selected for the Philippines.—The President has completed the selection of the medical officers to serve with the regiments of volunteer infantry to be organized for service in the Philippines. These appointments, together with the former service of the appointees, are as follows: *Surgeons, with Rank of Major.*—Ogden Rafferty, Captain and Assistant Surgeon, United States Army, late Brigade Surgeon Volunteers; Charles P. Mason, Captain and Assistant Surgeon, United States Army, late Brigade Surgeon Volunteers; John R. McDill, late Brigade Surgeon Volunteers, now Acting Assistant Surgeon, United States Army; Frank C. Armstrong, late Surgeon Twenty-first Kansas Volunteers; Thomas W. Chalmers, late Surgeon Twelfth New York Volunteers; Charles L. G. Anderson, late Assistant Surgeon, United States Army, now Acting Assistant Surgeon, United States Army; D. Albert Lieberman, late Surgeon Sixth Missouri Volunteers; Joseph N. Henry, late Surgeon Fourth United States Volunteer Infantry. *Assistant Surgeons, with Rank of Captain.*—John R. Hereford, late Surgeon First Missouri Volunteers; James C. Miner, late Surgeon First Arkansas Volunteers; Frank W. Foxworthy, late Assistant Surgeon One Hundred and Sixtieth Indiana Volunteers; Abram L. Haines, late Surgeon Two Hundred and Third New York Volunteers; James J. Erwin, late Assistant Surgeon Tenth Ohio Volunteers; W. E. Parker, late Acting Assistant Surgeon, United States Army; James E. Shellenberger, late Surgeon Third Ohio Volunteers. *Assistant Surgeons, with Rank of First Lieutenant.*—William H. Cook, Acting Assistant Surgeon, United States Army; Lomax S. Anderson, late Assistant Surgeon Fifth United States Volunteer Infantry; Leonard K. Graves, late Assistant Surgeon Two Hundred and First New York Volunteers; Ralph S. Porter, late Assistant Surgeon Second Illinois Volunteers; John A. Metzger, Acting Assistant Surgeon, United States Army; Patrick J. McKenna, late Assistant Surgeon Second United States Engineers; Albert H. Aber, late Assistant Surgeon Thirty-fifth Michigan Volunteers; John E. Boyd, late Captain Second South Carolina Volunteers.

OUR PHILADELPHIA LETTER.

[From Our Special Correspondent.]

LEGAL STEPS TO BE TAKEN AGAINST THE CHRISTIAN SCIENTISTS—INJURIES DUE TO THE FOURTH OF JULY—STATE BOARD EXAMINATIONS—CHILDREN'S HOSPITAL—PERSONAL—HEALTH NOTES.

PHILADELPHIA, July 10, 1899.

IT is an encouraging sign of the times to note that in both New York City and Philadelphia popular feeling against Christian-Science "healers" has been aroused to such a point of antagonism by the recent manipulations of this sect, that in the near future radical legal measures will probably be enacted to wholly suppress this menace to health and life. The half-dozen deaths which have occurred during the past three weeks, in different parts of this country, as the result of Christian-Science "treatment," have opened the eyes of the public to the enormity of this delusion, and have stimulated the medical profession to definite action along legal lines to suppress the evil. The lay press is doing a good work, at least here in the East, in exposing the fraudulent methods employed by these parasites of Christian profession, and the more the public learns of their widespread rascality just so much easier it will be to secure legislative support for laws aimed at the abolition of the practice of the Christian-Science fad. But the educational aid of the newspapers must be augmented by prompt and vigorous action by representative medical organizations before successful litigation may be hoped for. County, State, and national societies must take action singly and with combined forces. In Pennsylvania the laws of the Commonwealth seem to be adequate to justify immediate prosecutions, but in order to make haste slowly and to make sure of no unexpected abortion of plans, Dr. Henry Beates, in his official capacity as president of the State

Board of Medical Examiners, before taking legal steps in the matter, has requested the Attorney-General of the State to render an opinion as to the precise legal interpretation of the act for the regulation of medical practice as applied to Christian Scientists.

If, in the opinion of the Attorney-General, this sect may with impunity continue to evade the spirit of the law, although keeping strictly within the letter, another law will be agitated to absolutely prohibit their practices; if, on the other hand, his opinion is adverse to the Christian Scientists, immediate steps will be taken, both by civil injunction and by criminal prosecution. Dr. Beates' initiatory steps in this matter are being watched with a good deal of interest by the medical profession, and it is hoped that at last the exact status of Christian Science will be determined, and that drastic measures may be confidently resorted to for its suppression.

Philadelphia's contribution of accidents due to the prevailing manner of celebrating the Fourth of July places her high up in the list of cities where patriotism seems to be measured by maiming and wounding and loss of life. Three hundred accident cases, caused by fireworks, were treated by the city hospitals on the Fourth, not to speak of the many other unreported cases, cared for at the homes of the celebrators, by private practitioners. Of course the Mayor issued a special proclamation prohibiting fireworks, but as long as his edict is not enforced by the police, but rather regarded with supreme contempt by authorities and public alike, these needless casualties on the Fourth will continue. In every part of the city preventable suffering occurred, not only among the would-be patriots, but indirectly among the bed-ridden and nervous and sick in houses. Altogether, the Fourth of July nowadays has degenerated into a primeval orgie of noise, incendiarism and slaughter.

At the recent State Board examinations for licenses to practise medicine in Pennsylvania, all the candidates of the Eclectic school, ten in number, qualified, while ten out of the forty-one candidates appearing before the Homeopathic Board failed, and must be reexamined next November, to obtain the necessary permission to practise. The returns of the regular examiners have not yet been completed.

A roof-garden has just been given to the Children's Hospital by the president of the institution, Dr. T. W. Wilson, as a memorial to his sister, Mrs. Elizabeth Lewis. The new structure will afford fresh, cool air for the patients independent of the condition of the weather, and has been erected at a cost of $5000.

The total number of deaths in Philadelphia during the present week was 435, an increase of 15 over those of last week. Of the whole number of deaths, 189 occurred in children under five years of age. The returns of infectious diseases show 53 new cases of enteric fever, with 9 deaths; 50 new cases of diphtheria, with 11 deaths; 36 new cases of scarlet fever, with 1 death; and 4 new cases of cerebrospinal meningitis, with 3 deaths. The smallpox outbreak seems to have been entirely eradicated, no new cases having been reported here during the past seven days.

OUR LONDON LETTER.

[From Our Special Correspondent.]

LAWSON TAIT'S CAVE-BURIAL; CAUSE OF HIS DEATH; OTHER TRAITS—PROFESSOR SCHAEFER'S ELECTION AND LONDON'S LOSSES — MEDICAL REPRESENTATION IN THE SENATE AT LONDON UNIVERSITY—BRUSSELS MEDICAL GRADUATES IN LONDON—OSLER'S LECTURE — POLYCLINIC DINNER — THE "LANCET'S" APPRECIATION OF AMERICAN MEDICINE.

LONDON, July 3, 1899.

THAT great surgical genius, Lawson Tait, seems to have been determined to remain as eccentric in death as in life. A brief clause in his will directed that his body should be cremated and the urn containing his ashes placed in a niche in a beautiful cave in the grounds of his country-house in Wales, known as Gogarth Cave. Over the niche a simple slab is to be placed, bearing nothing but his name and age, and a short inscription to the effect that his life had been devoted to the attempt to save the medical profession from the shameful folly of animal experimentation and the delusion that the results so obtained were of any value in human medicine. It is extraordinary how many really great men seem to prefer to be remembered by their weaknesses, or even their follies, instead of by their real masterpieces. To think of a genius emblazoning upon his tombstone only the deeds for which he needs forgiveness—and oblivion! His other directions though equally unique, had a simple dignity about them which commands our respect and sympathy. No public gathering was to be held at his interment, or ceremonial of any kind, religious or otherwise, in fact only the members of his family were to know the date at which it occurred. These were observed to the letter. His body was taken to Liverpool by his brother-in-law and two executors, cremated, and the urn delivered to his widow, who, there being no issue, will alone and unaccompanied place it in the grotto, after such an interval as she judges best.

The cause of his death was renal calculus, probably causing a rupture of the ureter, as death came within twelve hours of the first symptom of trouble. He had had several attacks of renal colic, and two years ago an operation had been performed for the removal of a calculus from the urethra, so that, as his will clearly shows, the great surgeon was fully aware that serious complications might develop at any moment.

From his student days in his native Edinburgh to the very week of his death Lawson Tait loved fighting for its own sake, and when the "fog uv fightin'" was on him was perfectly reckless who or what he attacked, so that there was no need for him to study the gentle art of making enemies; they rose in swarms on every hand, but nearly all of them gave him credit for sincerity, bravery, and a remarkable dexterity with his weapons. And some of his most slashing attacks, as for instance, that upon the over-theoretical and over-scientific tendencies in modern medical education, with regrets for the departure of the old apprenticeship system, when at an association meeting at Birmingham, he advised his surgical brethren not to waste their time in the surgical exhibit but to ob-

serve and endeavor to imitate the dexterity of the Brummagem button-cutter, had a great deal of wholesome truth under their ferocity.

The chair of physiology in the University of Edinburgh has at last been filled by the election of Professor Schäfer of University College, London. This selection will meet with the unanimous approval of the entire medical profession, and considerable relief is expressed here as it was feared that the delay was due to some feeling in the board of electors in favor of a local candidate. It is, however, a far from creditable comment upon the absence of public spirit and the hand-to-mouth condition of affairs in both medical and university education in London that the metropolis of the world has lost within the past three months her leading pathologist, one of her best-known biologists, and her only distinguished physiologist to little Cambridge and poverty-stricken Edinburgh, simply because she is too stingy to pay them a decent salary. There is scarcely a chair of anatomy or physiology in London which has a respectable living attached to it. Most of them are in the antediluvian position of mere stepping-stones to surgery and practice of medicine. Only a week ago the "promotion" of a man who had begun to win a wide reputation as a scientific anatomist to the assistant lectureship in surgery was announced in the journals. That means, of course, the end of his prospects as a scientist, and the beginning of his degeneration into a mere operative-surgeon.

The composition of the senate of the proposed University of London has just been announced. Of its members 12 are to represent science, 10 the arts and literature, 6 medicine, while music, law, and theology have one each. Perhaps this may furnish at least the really great and adequately supported medical school which is so badly needed, but so intense is the conservatism, and so innumerable the petty jealousies and bickerings with which the scheme has to contend at every step, that it will be a matter of years or even decades before any actual teaching can be hoped for from it.

The annual dinner of the Brussels Medical Graduates' Association is announced for July 5th. It might at first sight appear strange that there should be a sufficient number of Belgian graduates in London to form an association, but the clue to the mystery is that the English degree of M.D. is so expensive and so outrageously difficult to procure that a large number of medical men go over to Brussels, where the coveted degree can be obtained by one-year's residence and study. There is a strong and growing desire here to resort to American medical colleges for this purpose.

The General Medical Council has published a brief but complete and continuous story of the Hunter persecution, in which it magnanimously forgives its victim and admits that its Penal committee may have been a trifle overzealous, but that nobody in particular was to blame, except, perhaps, poor Hunter himself, in placing his sign door-plate where the committee could see it when it happened to have its "fighting-socks" on.

The inaugural dinner of the London Polyclinic was a great success. Nearly 300 guests were present, representing the flower of English medicine, and the treasurer was able to announce at the close that the funds of the institution had reached the sum of nearly $25,000 and that some 200 students and attenders had enrolled themselves for the first term. Sir John Lubbock was in the chair and speeches were made by Sir. William Broadbent, Sir Joseph Fayrer, Mr. Jonathan Hutchinson, Dr. William Ord, and others.

The event of the week attracting the widest interest was the Cavendish Lecture of Professor Osler of Baltimore, before the West London Medical Society. An audience of nearly 400 physicians attended and the lecture was published in full in the current number of both the *Lancet* and the *British Medical Journal*. A curious little incident occurred during the proposal of the customary vote of thanks, which much amused the Americans present. The mover of the vote was enumerating the various grounds for welcoming Dr. Osler, and claimed him first as a Canadian and fellow-subject of the Empire, which evoked a mild ripple of applause, then as a representative of "our brethren across the Atlantic, the great American medical profession," and the speaker had to wait until the applause subsided before he could go on.

The *Lancet* devotes a long editorial to a critical commendation of Dr. Wilson's address at Columbus. It regards his estimate of the achievements of American medicine both just and moderate, scores deservedly a certain class of our journals, and cordially endorses his proposal to appoint a Minister of Public Health.

A FAMILY WITH CYSTINURIA—APPENDICITIS "LARVATA" — DIFFERENCE BETWEEN EPIDEMIC AND SPORADIC CASES OF CEREBROSPINAL MENINGITIS—MISTAKES IN DIAGNOSIS AFTER RUPTURE OF THE GALL-BLADDER—ENDOVESICAL PHOTOGRAPHS.

AT the Berlin Medical Society, May 10, 1899, COHN described a case of cystin calculus of the bladder which occurred in an eight-year-old girl. The stone was removed suprapubically and the child recovered. The interesting feature of this case was the fact that the mother of the child and five other children also at various times passed urine containing cystin, while the father and two grown sons always passed urine which was free from it. The occurrence of cystin in the urine of several members of one family was noted many years ago, but no such remarkable coincidence as this one has before been reported.

May 17th EWALD spoke of a type of appendicitis which he designated by the name "larvata." The symptoms are those of disturbed intestinal action with blood and mucus in the stools, and also loss of appetite and indigestion. The trouble goes on for years, sometimes better and sometimes worse, and usually the diagnosis is not made for a long time. When questioned the patient will admit having had a good deal of pain in the region of the appendix and ascending colon, and upon operation

these structures will be found to be much thickened. It has been suggested that the sudden improvement which follows an operation of this character does good by suggestion. Ewald was sure that this was not the true explanation in his own experience, for three reasons: All his patients so operated upon were not hysterical. They may have been nervous on account of the long-continued, painful attacks, but not hysterical. In the second place the suggestive effects of an operation, though they may be immediate and striking, wear off after a while and the old symptoms return. This was not true of his patients as some of them had remained well for over five years. But the strangest proof of all, that the effects of operation were not suggestive, is that patients who had painful symptoms due to disorders of the stomach or intestine continued to have the same symptoms after those referable to the appendix had disappeared.

SENATOR objected to the use of the term *larvata* in this connection. The cases of appendicitis to which the speaker had referred were not larvated in the sense that malaria may be, and nothing was to be gained by calling them so. They were, properly speaking, cases of appendicitis in which diagnosis was difficult.

At the Union for Internal Medicine, May 15th, STADELMANN spoke of the difference between epidemic and sporadic cases of cerebrospinal meningitis, having recently treated a case of the latter with success. The patient was a young man, and although at one time he was comatose, with Cheyne–Stokes respiration, and a thready pulse, he fully recovered. Several lumbar punctures were made, not for their therapeutic value, but to establish the diagnosis and to note the progress of the disease. As the case progressed toward recovery the turbidity of the fluid grew to be less and there was a destruction of the pus-corpuscles. The fluid contained a short rod-like bacillus.

At the Imperial Society of Physicians of Vienna, May 13th, HOCHENEGG presented a patient, a female aged forty-seven years, who had suffered from symptoms of intestinal obstruction, immediately after an intense abdominal pain. There was a doughy tumor at the umbilicus, and a diagnosis of volvulus of the transverse colon was made. Laparotomy was performed, and about six quarts of bile-stained fluid was washed out of the abdominal cavity. An old distended gall-bladder had ruptured.

FABRICIUS mentioned three cases of rupture of the gall-bladder in which a correct diagnosis was not made. In the first, on account of the umbilical swelling, a hernia was thought of; in the second, the tumor was so hard that it was mistaken for a fibroma; while in the third case, the escaped fluid penetrated the sheath of the rectus muscle and set up an abscess.

At the Vienna Medical Club, May 10th, LANG showed photographs of vesical mucous membrane taken during life by means of an improved cystoscope, his own modification. The actual negatives were about 3 mm. in diameter, but they were enlarged about ten diameters, so as to make it possible to see details more clearly. The instrument also prevented any trembling, which is certain to spoil a photograph of this sort. The instruments were sterilized by exposure for an hour and a half to formalin vapor.

SOCIETY PROCEEDINGS.

THE NEW YORK ACADEMY OF MEDICINE

Stated Meeting, Held Thursday, June 1, 1899.

THE President, DR. WILLIAM H. THOMSON, in the Chair. The paper of the evening was by DR. HENRY D. CHAPIN, and was entitled "The Treatment of Summer Diarrhea in Infants" (see page 65). The discussion was opened by DR. L. EMMETT HOLT, who said in brief: The most important consideration as regards the lessening of the death-rate from diarrhea among infants in our large cities in the summer time is the matter of intelligent prophylaxis. For this the most practical means at hand would seem to be the dissemination of literature among the ignorant classes. In the tenement-house district, especially, is the information scattered by leaflets containing definite directions as to the feeding and care of children in the hot weather of special importance. There is no doubt in the minds of any who have had experience in this matter of the great possibilities for good that are contained in this work.

Dispensary practice among the very poor serves to show how extremely necessary seemingly the most obvious information on such matters is. The most ludicrous, if they were not so serious and apt to be so fatal, mistakes are made by mothers who might easily be expected to know better. The distribution of a leaflet containing the necessary directions as to the care of children in summer was contemplated two years ago, but for some reason the idea was abandoned. It is to be hoped that the New York City Board of Health will again take up the work in this line, for there is not the slightest doubt that great good can be accomplished in this way.

As to the actual treatment of diarrheic conditions time is the most important element for their cure. If they can only be treated in time there is but very little danger. Twelve hours is more precious for therapeutic purposes at the beginning of the sickness than is a whole week of medication later on. The trouble is, however, that beginning diarrheas are neglected. They are attributed to teething, to a cold, to the weather, and it is thought they will get better of themselves or with some simple household remedy, and with some slight modification of diet. In twenty-four hours, perhaps, a fatal diarrheic condition that defies all treatment is lighted up. Four or more movements a day in the child are allowed to occur for some days without seeking relief for them. The infection gains a firm hold by irritation of the intestine, and then cannot be eradicated before it has produced serious effects.

In children with whom simple milk does not agree the dilution of the proteids of the milk by some carbohydrate is often of great service as a prophylactic against diarrhea. A number of the cereals may be used for this purpose, and there is no doubt that they have a good effect.

Arthur Keller has shown by a recent series of experiments that in vitro, at least, the presence of carbohydrates prevents the putrefaction of proteids. We thus get a scientific confirmation of what we have known for a long time clinically to be the case, that intestinal putrefaction of milk is prevented by mixture with cereals.

Once the diarrheic condition has asserted itself there should be no hesitation as to taking radical measures. Mere modification of diet will not suffice. The practitioner is tempted to temporize, and hopes that the condition will not prove serious. This is always a serious and may prove a fatal mistake. Stop all food at once until there is a decided improvement in the intestinal condition. The indication is to get the stomach and intestines empty as soon as possible. For this irrigation of the intestines is the best therapeutic means, not once only, for after the lower bowel has been washed out for some hours, other material comes down into it, and this too may be removed, and some of the toxic absorption and a certain number of the intestinal micro-organisms be gotten rid of. In ordinarily severe cases irrigation may be practised four or five times a day. In bad cases when the temperature runs up to 105° F. the intestines should be irrigated every two hours, at first with warm water (100° to 105° F.) to get its cleansing, relaxing effect, and then with cooler water to help bring down the temperature. Washing out the stomach is also good, especially at the beginning of an attack.

All food should be stopped absolutely for twelve hours or longer. Water may be given freely, and stimulants are often good. It must be remembered that even sterile milk does not stay sterile long in an infected digestive tract, and that its presence only irritates, while the milk itself forms an excellent culture medium for the growth of micro-organisms that are present.

DR. ABRAHAM JACOBI said that there are times when one feels that one has not lived in vain. Such occasions almost compensate, though they are seldom enough, alas, for the number of times when one feels that one has accomplished nothing. It is refreshing, indeed, to hear the recommendation to mix cereals with milk given so freely after one has been teaching the doctrine for thirty to forty years. Years ago he counselled the suspension of the casein of the milk in oatmeal or barley-water by proper dilution. It certainly produces a more flocculent curd. Of late years the idea has been taken up very enthusiastically in certain parts of Europe. Professor Heubner, for instance, who holds Henoch's chair at Berlin, has taken up the matter of the mixture of milk with cereals, and is teaching it very emphatically.

With regard to leaflets to be distributed to the poor containing instructions for the feeding of infants, he believes very fully in their usefulness. More than twenty-five years ago at the request of the New York Board of Health he prepared such a leaflet, and for nearly twenty years it was regularly distributed. About five years ago its further dissemination was given up for some unknown reason. There is only one thing in the old leaflet that it would seem desirable to change and that is the direction to add bicarbonate of soda to the milk when it cannot be procured fresh. Adding to the alkalinity in this way only makes the milk a better culture medium for micro-organisms and this should be avoided.

It is not by any means a new observation that the presence of carbohydrates prevents putrefaction. It has been known that they readily undergo fermentation and that in this process free acids are formed. The presence of free acid acts as an inhibitory agent to the microbes that produce putrefaction. The use of cereals in baby-food is then at once a preventive and a curative agent in certain intestinal disorders.

It has long been the custom to say that no amylaceous substances should enter into a young infant's food because it has from nature at an early age no ferment capable of digesting starch. Even admitting this, however, the addition of carbohydrates to the child's dietary supplies a certain amount of ballast to artificial food. In mother's milk this ballast is provided mainly in the fat which constitutes 10 to 12 per cent. of the excrement of nursing babies. It is not true, however, that even very young infants have no ferment capable of digesting starchy material. The saliva of a newly born child, and it is wrong to say that there is no saliva at this age, will dextrinize starch as any one who wishes may prove for himself. That the parotid gland of a healthy fetus after three months of age contains an amylolytic ferment has been proven over and over again. The submaxillary gland contains a similar ferment to that in the parotid gland from the beginning. Starch digestion is then very natural to the infant and the mixture of this material in artificial food provided for it is indicated at all ages.

DR. KOPLIK said that he thought preventive measures should be more insisted on than had been the case in the discussion, and especially that summer diarrheas should be treated rigorously in their very earliest incipiency. A slight frequency of stools, especially if they are of watery consistency and if accompanied by the slightest inclination to vomit, should be the signal to stop all feeding at once. Then the bowel should be promptly cleaned out and the stomach also if thought advisable. The one thing that must be the doctor's object is to prevent the development of serious diarrheas. Very little can be done for the severer forms of the affection and prophylaxis is our only hope.

Here in New York City we are at least twenty hours away from our milk-supply, so that there is no hope of getting anything like fresh milk. Under these circumstances he was surprised that the necessity for the sterilization of all milk to be given infants had not been not more insisted on by the preceding speakers. After thorough sterilization the milk should be cooled rapidly in order to prevent the separation of the cream from it to too great extent. Pasteurized milk though much confidence had been placed in it for the prevention of summer diarrheas has not been found satisfactory. It is liable for reasons not well understood just yet to set up slight diarrheic conditions and cause some gastro-intestinal irritation so that its use is not advisable.

As to the mixture of a certain amount of the cereals with milk for infant feeding his opinion accords more

or less with what had been said by others. The current of medical sentiment is settling in this direction. In some cases certainly they give excellent results, in others they are very disappointing. There seems to be no special method of deciding in any given case whether they will agree with the little patient or not so that the only thing is to try their effect and note the results.

As to drugs very little dependence can be placed on them in the severe diarrheas of the summer time. When a practitioner thinks that he does a great deal of good with drugs he is evidently not an acute clinical observer. Divided doses of calomel are often claimed to be of service, but of late years he has learned to distrust any specific action this might have through its effect on the biliary secretion, or because of its supposed intestinal antiseptic effect. Opium he would never advise. It sometimes does some good by quieting the child, but should be given only in very small doses. It is better to have a restless child than one in whom opium helps on a fatal stupor.

In a severe case of summer diarrhea the first indication is to wash out the stomach, remove fermenting material and prevent the absorption of toxic materials from the gastro-intestinal tract. This lavage need not be repeated. The intestines should be washed out frequently, however. It removes peccant material; it stimulates peristalsis, which also helps to remove undesirable irritating substances, and it supplies water to the infant, a very useful measure since it is well known that the child is water-starved. A stiff rubber rectal tube, such as is used for adults, may be used without fear. Too much pressure should not be employed, however, in forcing water into the intestines as it is possible to burst them. The irrigator should not be placed more than one foot above the patient. It is a good plan to try and leave considerable water in the intestine when the irrigation is concluded. About a pint of normal salt solution should be employed. This is absorbed better than simple water and besides is less irritating. After improvement begins it is not easy to go back to milk at once. At first it should be well diluted to insure its not setting up a relapse to the former condition.

DR. GRAHAM LUSK detailed some observations that he had made on young pigs. Beginning when they were two days old he had fed them on skimmed cow's milk. To a certain number he gave only cow's milk skimmed, to others skimmed milk to which two per cent. of sugar was added, to others skimmed milk with two per cent. of dextrose. Those fed only on skimmed milk did not thrive. They were thin and scraggy looking and failed to grow properly. Those fed with skimmed milk and sugar did reasonably well, while those fed also on dextrose grew vigorously. This substance is a cereal product, so that these recent observations would seem to confirm Dr. Jacobi's long-standing opinion as to the value of cereals, when added to milk, for the feeding of the very young.

In closing the discussion DR. CHAPIN said that despite certain prejudices in the matter that are rather widespread, a certain small amount of cereals does not cause, but rather checks diarrhea. They are not, it is true, as Dr. Koplik said, always effective, but milk diluted with oatmeal or barley-water always is tolerated better than if diluted with plain water. He thinks that as a rule pasteurization suffices to make milk safe for infant consumption. In very hot weather it is safer to sterilize. It must be remembered, however, that it is not enough merely to stop fermentation in the milk and that the destruction of the micro-organisms in it makes it fit for use. If the milk is old and fermenting processes have been going on in it for some time changes have been made in the substance of the milk that may make it unfit for use. It would be a great advantage if we could obtain fresher milk in this city than at present; if instead of receiving milk 20–24 hours old, or even older, we could obtain milk 10–12 hours old. This constitutes a field for the most serious effort and one in which successful effort will be most fruitful in saving the lives of city children.

THE AMERICAN ORTHOPEDIC ASSOCIATION.

Abstract of the Proceedings of the Thirteenth Annual Meeting, Held at New York, May 31, and June 1 and 2, 1899.

THE president, DR. W. R. TOWNSEND of New York, opened the meeting with the reading of the annual address. He reviewed the history of orthopedics in America and showed that the profession of New York City had been mainly instrumental in bringing about the improvements in this branch of surgery in America and throughout the world. Four names especially stand out: James Knight, the philanthropist; Charles Fayette Taylor, the mechanical genius and enthusiastic leader; Lewis Sayre, the impressive teacher and eminent author; and Henry G. Davis, who revolutionized the treatment of joint and spinal disease and whose originality and genius made him the father of American orthopedic surgery.

DR. E. H. BRADFORD of Boston then read a paper, entitled "In Memoriam of Dr. Charles Fayette Taylor," in which he referred to Dr. Taylor as the founder of modern practical orthopedics and said that every meeting of the American Orthopedic Association is and would ever be a tribute to his work.

The next paper, on "Degeneracy as a Causative Factor in the Production of Scoliosis" by DR. JOHN RIDLON of of Chicago, will appear in a subsequent issue of the MEDICAL NEWS.

DR. E. G. BRACKETT of Boston then read a paper prepared by himself and DR. E. H. BRADFORD, entitled "The Forcible Correction of Lateral Curvature." He said that it is well known that even bone will yield to continuous pressure. The difficulty has been the retention of affected parts in positions in which pressure could be exercised. When the patient is in the recumbent position the advantage of the superincumbent weight is lost as an aid. A properly fitting and applied apparatus can be made to avail itself of this. The cast should be applied in a Bradford frame, which enables one to do away with the disadvantage of the superincumbent weight and use it as a corrective.

Pressure should be applied at three points, particularly behind, of which that of greatest deformity is the principal one, and others above and below while counter-pressure is exercised on points on the opposite side of the body. The great objection to the use of jackets in scoliosis is that the point of greatest counter-pressure is over the concavity of the curve of the deformity on the opposite side. The tendency this has to emphasize the deformity may be corrected by a collar around the neck that takes up most of the counter-pressure.

The cases for which forcible correction with retention as far as possible in the corrected position is necessary are those in which there is bony change and in which bony development is still expected. The greater the deformity the more is this method indicated. It serves a very useful purpose in children who are too weak for gymnastics, or who are not sufficiently under control to be put through regular exercises. The amount of correction that follows three or four applications of the jacket is often wonderful. After the primary improvement, however, there is a period of comparative standstill during which other methods may be used with advantage.

DR. TESCHNER of New York followed with a paper, entitled "The Heavyweight Treatment of Post-paralytic Deformities, Including Lateral Curvatures." He has had six cases in which he has been able to restore function to seemingly degenerated muscles by graduated exercises so arranged that finally eight- to ten- or even fifteen-pound dumbbells were employed. He has the patient, with frequent rests, put forth each time all the strength he is capable of. Three of his cases were obstetric hemiplegias with atrophy of muscles, yet a great deal of improvement took place. Reaction of degeneration in muscles disappeared during the course of the exercises and were replaced by normal muscular reactions. He considers that the muscular fibers intact in the muscle are developed to their fullest extent, and that there is under the stimulus of exercise an actual development of muscle substance.

DR. WALTER TRUSLOW then read a paper, entitled "Some Remarks on the Class Method of Gymnastic Treatment in Lateral Curvature," which will appear in a subsequent issue of the MEDICAL NEWS.

DR. AUGUSTUS THORNDIKE of Boston read a paper, entitled "Congenital Deformities of the Spine." He discussed the two forms, spina bifida and rachischisis, and exhibited illustrations of the various forms, and of their association with forms of anencephalus, meningencephalocele, and other congenital abnormalities. Before operation the tumors need to be carefully protected from abrasion and infection. There are two practically absolute contraindications to operation, marasmus and the presence of hydrocephalus as a complication.

Rupture of the sac is usually enough to justify immediate operation as infection is almost sure to follow. Convulsions, if due to internal pressure, may sometimes be relieved by puncture and evacuation of the sac, but this gives but temporary relief and is usually employed only in acute cases where the operator is not ready for more radical measures. Two methods of radical cure are employed, excision and the injection of iodin. Excision is the ideal operation. Iodin has undoubtedly cured certain forms of simple meningocele, but it is so difficult to distinguish them from the others that excision is preferable.

DR. L. A. WEIGEL of Rochester, N. Y., then read a paper, entitled "The Diagnostic Value of Radiography in Orthopedic and General Surgery, Illustrated by Stereopticon Views." He showed that it is possible to detect even small foci of tuberculosis of bone by the X-rays. In the head of the tibia and in the os calcis by a number of views it was demonstrated that lighter areas due to porosity of the bone occurred in the radiograms, when there was only tenderness and usually no swelling present in the vicinity. In hip-joint disease he has found the pelvis on the side of the lesion markedly smaller and atrophic as compared with the other side.

In a series of injuries in which at the time no evidence of fracture could be obtained, yet serious deformity followed, the Röntgen-rays had shown various bony lesions, a fracture of the olecranon, a comminuted fracture of the acromion, fractures of the styloid process of the radius, followed by the throwing out of a large amount of plastic material, etc. In a case of supposed forcing of the tibia and fibula apart the astragalus had been found comminuted. Fractures of the neck of the os calcis were demonstrated in obscure cases. Fibrous deposit between joint surfaces can be detected even in such obscure situations as the lower jaw. Gonorrheal rheumatism in some cases produces a change in the periosteum and ends of the bones that may be demonstrated in the same way. Spontaneous dislocation of the hip such as occurs in typhoid was illustrated and its progress demonstrated.

DR. W. BURTON HOPKINS followed with a paper on "Pigeon Toe." He considers that there are quite a number of cases of this deformity amenable to direct treatment. As a rule parents consider this turning in of the toes at first in the child as they do a stoop or a swaying of the back, as a childish trick. In some cases one toe turns in much more than another. For these he has invented an instrument which turns the toe outward just as the heel comes down. At first he employed a spring set in the heel of the shoe; now he has modified the instrument so that it works on ball-bearings and is practically indestructible.

The report of the Committee on Recording Lateral Curvature was to the effect that photography constitutes the best method available at present for recording these spinal deviations, the method least open to error because of the personal equation, the one that is easiest to make and can be best understood by the general practitioner as well as the specialist without difficulty. As a means of controlling photographic records the method recommended by Kirchoff and somewhat modified by Bracket is suggested as simple and reliable. Its essential feature is the dropping of a plumb-line from the neck and measuring the distance of various parts of the scoliotic curve of the spines of the vertebræ from it in the various regions.

On motion of DR. WILSON of Philadelphia the report

of the committee was accepted, but no method of recording lateral curvature was recommended by the Association because none as yet described seems sufficiently definite and accurate.

DR. JOEL E. GOLDTHWAIT of Boston read a paper, entitled "A Study of Pott's Paraplegia as Affected by Correction of the Spinal Deformity." In eleven cases he has found that correction of the deformity has always been followed by immediate disappearance, *i.e.*, within a few hours or less of the paraplegic symptoms. The improvement has persisted in all the adult cases, though there has been some recurrence of symptoms in children. No force other than the patient's own weight was used in securing the correction.

DR. GOLDTHWAIT then read a paper, entitled "Osteo-arthritis of the Spine, with Report of Nine Cases." Osteo-arthritis of the spine or spondylitis deformans is really only the spinal form of a disease that may extend to all the joints. So far thirty-five cases under different names have been reported in the literature. To these the speaker adds nine.

The typical symptom is the rigidity of the spine which may begin in spasm of the muscles and then gradually ends in a fusion of the vertebræ. The ribs may become involved and the whole thorax become immovable when respiration will be entirely diaphragmatic. Improvement often occurs after the disease has reached its acme.

Certain text-book declarations as to the disease are not borne out by careful study of the cases. It is not exclusively a disease of the old but occurs oftenest in early middle life and not infrequently in closing adolescence. It is not limited to the large joints as is often stated but may involve the fingers. It may not give the characteristic deformity of kyphosis or scoliosis but may make the spine rigid with all its curves preserved.

In the group of cases that are usually supposed to come under the head of spondylitis deformans there are really either two distinct diseases or two very divergent types of the same disease. The one form is more properly designated a rheumatoid arthritis and is atrophic in character and leads to the disappearance of portions of the normal joint; the other is a productive osteitis. Nodular projections occur on the long parts and these fuse together producing the anchylosis that is noted as such a prominent sign of this type.

As to the cause of the ailment in either of its forms nothing is definitely known. Gonorrheal rheumatism and other unusual forms of arthritis have been thought to be responsible for it, but their etiological connection is not proven. Dr. Goldthwait finds in his own cases and in certain ones reported in the literature that patients subjected to extremes of temperature are especially liable to suffer from it, firemen, stokers, engineers, and the like. As to treatment, stimulating baths are good, but frequent hot baths, though employed by some, are debilitating and do harm. Regarding hot-air treatment the same is true; it must not be employed so much as to weaken the patient.

DR. G. G. DAVIS of Philadelphia read a paper, entitled "Operative Treatment of Congenital Dislocation of the Hip." He described two new instruments for making or deepening the acetabulum in these cases; one a heavy spoon-shaped gage chisel, the other a half rose-burr, somewhat like a trephine, especially adapted for making a shoulder against which the head of the femur would rest in the new acetabulum.

DR. W. J. TAYLOR of Philadelphia then read a paper, entitled "Report of a Case of Dorsal Dislocation of the Hip Occurring Spontaneously During the Course of an Acute Osteomyelitis of the Neck and Shaft of the Femur." The case was thought at first to be one of tubercular hip-joint disease; an abscess formed and opened of itself. After this spontaneous dislocation upon the dorsum ilii took place. This led to suspicion as to the cause of the process, when a free incision showed that the original affection had been an acute osteomyelitis of the shaft of the femur. The process involved the bone for some distance from the joint, and abscesses had formed beneath the periosteum and within the bone itself. These were evacuated and thoroughly scraped, though the patient's low condition did not allow of doing all that was desired in the matter. Recovery took place with four inches of shortening.

The disease started at the epiphyseal line which is within the capsule, and rupture took place into the joint. Distention of the capsule was the mechanical factor favoring dislocation, and the mechanism of the lesion is exactly the same as that which takes place in typhoid. The practical point to be borne in mind is that relief of the distention of the capsule may prevent spontaneous dislocation, if aspiration, or puncture, and drainage is done in time. In general, harm to joint structures is done by allowing distention to continue long in any joint, so that the advisability to removing some of the fluid should always be borne in mind.

DR. W. E. WIRT of Cleveland, Ohio, followed with a paper, entitled "Reduction of Congenital Hip Dislocation by the Lorenz Method." If taken at an early age he has found that very good results can be obtained by the bloodless method of Lorenz in the severest cases of congenital dislocation of the hip. In one of his cases relapse occurred because no apparatus was used after two months. He employs a bandage with a pressure pad to retain the head of the femur in place. This must be worn for 4–6 months to insure against recurrence of the deformity. The use of a high heel on the affected side as recommended by Lorenz is also of use in keeping the bone in place. Sometimes it is extremely hard to get the head of the femur down to its place, and Dr. Wirt has used as high as 200 pounds traction before the operation and yet had difficulty during the operation. The younger the children when operated upon the less the difficulty and the better the result.

DR. H. M. SHERMAN of San Francisco then read a paper, entitled "Congenital Dislocation of the Hip." He has performed eleven bloody or open operations according to the Lorenz method. In these the results have been as follows: Three are stable, *i.e.*, the head of the femur remains in place but there has been anchylosis; one is stable and there is a certain amount of motion. There is also

a certain amount of shortening, and for some unknown reason this is increasing. One is stable and anchylosed and the anchylosis has been broken up giving motion, but the typical gait of the short-necked femur remains. Three luxated again and are failures. Both hips of one child operated upon anchylosed, causing a very awkward gait which was improved by the recurrence of luxation of one hip. He has operated on thirteen hips by the bloodless method, of which seven have recurred. Lately he has operated with the Lorenz manipulations, but has convinced himself of the presence of the head of the bone in the acetabulum by an incision and actual palpation of the conditions. He has been better satisfied with this method though about one-third of them have definitely reluxated and a certain number of them are still in splints and the ultimate results are uncertain. He thinks there must be some way of correcting the deformity, but up to this we have not found the way.

DR. R. T. TAYLOR of Baltimore then demonstrated the kyphotone, a machine for the forcible correction of the deformity of Pott's disease. It consists of an arm attached to the upright from which the patient is suspended, by which pressure is brought to bear immediately over the most prominent part of the deformity of Pott's disease thus securing the greatest possible amount of correction as the jacket is put on. He also exhibited an inclined plane of nickeled steel-tubing, light and easily adjustable, and eminently cleanly for use in fractures and the treatment of deformities.

DR. ROYAL WHITMAN of New York then read a paper, entitled "Further Observations on the Treatment of Congenital Dislocation of the Hip. Exhibition of Patients," which will appear in a subsequent issue of the MEDICAL NEWS.

DR. T. HALSTEAD MYERS followed with a paper on "Cases of Coxa Vara and Congenital Dislocation of the Hip. Exhibition of Patients." The case of congenital luxation of the hip was the first one operated on by the Lorenz method in this country and the result is perfect.

Patients suffering from different varieties of orthopedic disease were then exhibited by Drs. Ketch, Waterman, Taylor, and Townsend, after which DR. A. M. PHELPS of New York read a paper, entitled "Report of Cases of Tubercular and Purulent Abscesses of Joints, Treated with Pure Carbolic Acid." He said that he first washed his hands in pure carbolic acid and, after allowing it to remain for a minute, washed it off with alcohol. This he considers demonstrates that alcohol is the antidote to carbolic acid locally. Taking advantage of this he swabs out all cavities thoroughly with pure carbolic acid, and then washes them out with alcohol and later with water. In tuberculous cases he obtains primary union by means of this even in long-standing suppurative cases. Where the patients remained in the hospital for months before they now stay weeks. In three or four weeks they may be discharged cured, while four months did not seem long before.

In cases of erysipelas with high fever the effect of the application of carbolic and its subsequent neutralization had been most marked. A drop of four to five degrees in temperature took place, and the erysipelatous process ceased to spread. In Dr. Phelps' own case when septic infection had set up lymphangitis the same sort of an application had lowered the fever, relieved the symptoms, and made him feel much easier. What theory explains this action he does not know; perhaps there is a change produced in the subcutaneous layers with absorption of phenic or other albuminoids. The effect is certainly produced, and there would seem to be great promise in the use of the remedy in the various affections mentioned.

DR. ARELLANA, Dr. Phelps' assistant at the City Hospital of New York City, read a paper on "Cases of Erysipelas with High Temperature, Treated by Applications of Carbolic Acid, with Subsequent Neutralization by Alcohol." In a series of some ten cases of erysipelas of the face and neck, with temperatures ranging from 104.5° to 105.5° F., applications of pure carbolic acid were followed in from eight to twelve hours by a drop of from 3° to 5°, and the process ceased to spread. In about one-third of the cases a second application had to be made, but never a third. No other method of treatment, local or internal, was employed, and all of the patients recovered, though it is among such that fatal cases of erysipelas are often found. In none of the cases has there been any smoky urine, or any change in the urinary secretion, and no sign of any carbolic-acid poisoning has developed, though they have been carefully looked for.

DR. G. G. DAVIS of Philadelphia presented a new osteoclast and a new instrument for flat feet and for paralysis with drop-foot to be worn inside the shoe.

DR. WIRT of Cleveland presented a new knee-brace for correcting deformity and a pocket goniometer.

DR. S. L. MCCURDY presented a new apparatus for the support of the head in cervical Pott's disease with supports on the sternum and back below and chin and occipital pads above.

DR. H. M. SHERMAN of San Francisco read a paper, entitled "Position Symptoms in Joint Disease." He said in brief that the position assumed in joint affections is a valuable clinical symptom of the amount of inflammation present and the stage of the affection and has long been acknowledged as such. There has not been the same agreement as to the reason for the positions observed. The French explanation that the amount of the effusion into the joint causes the various positions by tension on the capsule or by its rupture late in the affection is no longer accepted. The idea that one set of muscles is stronger than the other and that both being irritated the stronger flexors overcome the extensors supposes a struggle for superiority between muscles that does not exist. Dr. Sherman considers that the position assumed is due to the reflex call for rest for the affected parts which causes not a spasm but a tonic contraction of muscles fixing the limb in a definite position where there is least discomfort. When this tonic contraction relaxes for any reason, as during sleep, then there occur the starting pains so often noted. This muscular fixation is, however, but a small part of the mechanism as bones and ligaments and capsular tissues share in the reflex demand for rest.

DR. B. E. MCKENZIE of Toronto read a paper, en-

titled "Some Salient Points in the Treatment of Hip Disease," which will appear in a subsequent issue of the MEDICAL NEWS.

DR. C. L. STARR of Toronto followed with a paper on "The Conservative Surgical Treatment of Tuberculous Disease of the Joints." He considers the ideal surgical treatment for a tuberculous focus in bone to be to cut down and remove it before it had invaded important structures and caused extensive destruction of tissue. The first definite focus of tuberculosis is situated at the epiphysis, which accounts for the fact that the very young and the old are not attacked. In the very young the hyperemia here increases the resistive vitality; in the old, fatty changes have made the parts a poor culture medium for the bacillus tuberculosis.

There are certain cases in which we are unable to diagnose the presence of a tubercular focus before it has invaded the joint. Pain is not very valuable as a diagnostic sign of the position of a lesion because of its liability to be reflected from and referred to other points than the affected one along nerves. Tenderness is, however, of the greatest service and will very often enable one to diagnose with assurance.

The indication is to open up at once and scrape away all the diseased bone. In the head of the tibia or in the malleolus this is often very feasible and can be done successfully in the femur. The cavity made should be swabbed out with carbolic acid or with chlorid of zinc and then packed with iodoform gauze. Healing in selected cases is prompt and complete. So far no recurrences have been noted.

DR. A. B. JUDSON then read a paper, entitled "Additional Views on the Treatment of Hip Disease." He said that a great deal can be done to correct the gait of cured hip-joint disease with shortening, by training the patients to walk. Girls with two or three inches of shortening often walk marvelously well. Boys more neglectful with less shortening walk very awkwardly. Military training and the keeping of time is a good drill for these children. The parents must be impressed with the idea that constant watchfulness and care in the matter of the best possible gait will lead to improvement in this matter. A deliberate turned step must be adopted. If this care of the walk is attended to the surgeon need never fear anchylosis in a bad position.

DR. S. H. MCKIM of Baltimore then read a paper prepared by himself and DR. R. T. TAYLOR, entitled "Some Clinical Features of Rheumatoid Arthritis." Among the clinical features of the disease not usually pointed out the authors dwelt on the frequent occurrence of polyadenitis of the lymphatic system and enlargement of the spleen. The systems of glands especially affected are those nearest the diseased joints, the epitrochlear, the inguinal, and the posterior cervical. Slight exophthalmos often exists, and there is frequently some fever. The febrile course is of two types, either acute, lasting for but a few days at the beginning, or continuous for some time when it is milder. Garrod still believes that the disease is a gouty or rheumatic manifestation, but most of the authorities agree with Osler, who considers it a nervous condition. The differential diagnosis must be made from subacute rheumatism, in which the changes around the joints are fibrous in character and not the nodular enlargements met with in the productive variety of rheumatoid arthritis. Charcot's disease occurs in older people as a rule, though at times, too, in young people, but gives clear evidence of being trophic in character. It must be borne in mind that the starting pains at night may occur in rheumatoid arthritis as well as in tuberculous joint disease and this fact must be remembered in making the diagnosis. Very little seems to be accomplished by any treatment. Ordinary rheumatic, alterative, or absorptive remedies appear not to affect the course of the disease or any of its symptoms. Even the breaking up of adhesions under ether seems to do little if any good.

DR. J. D. GRIFFITH of Kansas City then read a paper on "A New Method of Reducing Ancient Dislocations of the Humerus by Open Incision." In three cases he found that by cutting the long head of the biceps the head of the bone slipped back comparatively easily. As a number of deaths have been reported from the use of force in these cases because of rupture of the axillary vein, this bit of technic seems worth bearing in mind. He exhibited an instrument shaped like a very large periosteal elevator, devised to assist in throwing the head of the humerus back into the glenoid fossa.

DR. S. L. MCCURDY of Pittsburgh read a paper on "Heat as a Therapeutic Measure." In chronic joint disease bacterial growth may be inhibited by keeping the joint subject to temperatures of 140° F. for hours and metabolic processes are increased and absorption of inflammatory products take place. The difficulty is that living tissues cannot be elevated in temperature sufficiently to accomplish either of these ends without hurting cell-life so much as to do more harm than good.

DR. B. E. MCKENZIE of Toronto read a paper, entitled "Surgical Intervention in Spastic Paralysis (Cerebral Palsies)." He said that these unfortunate patients, owing to the prevalence of the idea that the basis of their symptoms is a lesion of the central nervous system, and that nothing, consequently, can be done to permanently improve them, have received in the past too little attention. He has found that all of them are benefited by properly directed treatment. He cuts the tendons of spasmodically contracted muscles and puts the limbs up in casts to secure elongation on union. The adductors he has found especially subject to contraction and after section he fixes the legs at an angle of 90°. Relapses may occur and then he tenotomizes again or does a myotomy. The children are soon able to walk and their association with other children soon improves their mental qualities. They grow much more intelligent. Apparatus can be dispensed with after a time, or need be worn only at night. Training and gymnastic exercises serve to get the children into better general health. The absence of the reflexes set up by the continuous spasm gives the child an opportunity to develop physically and mentaliy in a way that is most satisfactory.

DR. A. B. JUDSON of New York then read a paper,

entitled "Prothesis, a Branch of Orthopedic Practice." He exhibited sets of apparatus designed to hide deformity and make up for various disabilities. A perfectly normal looking shoe for considerable shortening after hip disease, the foot being supported on a cleverly constructed inclined plane within it, was the most striking.

DR. DANIEL LA FERTE of Detroit, Mich., then read a paper, entitled "The Cause of Failure after Phelps' Operation for Club-foot." In his experience failure has been invariably due to the fact that not enough tissue was divided to permit correction of the foot. Everything that resists the reposition of the foot to a normal position and a little beyond should be freely divided. This may require division of certain ligaments of the joints, as well as skin, fascia and muscles; even the posterior ligament of the ankle beneath the tendo-Achillis may require division.

DR. ARTHUR GILLETTE of St. Paul, Minn., followed with a paper, entitled "The State Care of Crippled Children." He stated the necessity for State care for such children when relatives are poor, and detailed the successful effort that has been made in Minnesota in securing State aid for an orthopedic department. The success achieved has made the gaining of further State aid easier, and now the outlook for orthopedics for the needy is good. Patients are taken only on the recommendation of physicians and the manner of conducting the affair through the Legislature, may prove of help to others who have similar objects in view.

DR. RUSSELL A. HIBBS of New York then read a paper, entitled "A Preliminary Report of a Study of Shortening of the Tibia in Connection with Tuberculous Disease at the Hip." In a previous paper he had shown that in 110 cases of hip-joint disease there was distinct shortening of the femur. The most shortening occurred in non-suppurative cases so that it was due not merely to loss of bone but to nervous or circulatory causes. He has now examined the tibias in 41 cases, and has found that this bone also is shortened in most cases, and and in many more than the femur of the corresponding side. There is then a nervous or circulatory disturbance that interferes with the nutrition of the whole limb.

REVIEWS.

AN EXPERIMENTAL RESEARCH INTO SURGICAL SHOCK. The Cartwright Prize for 1897. By GEORGE W. CRILE, A.M., M.D., PH.D., Professor of the Principles of Surgery and Applied Anatomy in the Cleveland College of Physicians and Surgeons. Philadelphia: J. B. Lippincott Company, 1899.

ANY experimental evidence tending to throw light upon our knowledge of surgical shock is a welcome addition to the literature of the subject. Dr. Crile has accumulated in his researches some testimony as to the nature of this most dreaded of surgical sequels, which while not entirely new, is, nevertheless, important on account of its practical bearings.

His researches embraced operations upon animals in all regions of the body. Operations upon the brain and the abdomen seemed, under certain conditions, to provoke shock more easily than operations in other parts of the body, while procedures upon the male genital organs and dragging operations in the vicinity of the pylorus and gall-bladder seemed also prone to call forth this condition. The author concludes as a result of his work that shock is primarily a vasomotor disturbance, influenced indeed by cardiac and respiratory changes. Hemorrhage the author finds a powerful factor in producing shock as it is responsible for the great change in the vasomotor efforts to maintain a mean blood pressure. The best treatment is prophylactic; but with the condition once established, the author finds experimentally that the usual clinical treatment with heat, strychnin stimulation, and saline infusions is based upon sound physiological principles.

The essay is the result of hard work and a large number of experiments and is admirably written. It deserves a high place in the literature of the subject with which it deals.

INTERNATIONAL CLINICS. A Quarterly of Clinical Lectures on Medicine, etc., with specially prepared articles on Treatment and Drugs. By PROFESSORS and LECTURERS in the Leading Medical Colleges of the United States and Foreign Countries. Vol. I. Ninth series. Philadelphia: J. B. Lippincott Company, 1899.

THE present volume contains a most varied assortment of good things, and keeps up the reputation of the Quarterly for the presentation of practical material of present interest and actual value to the practitioner. Professor H. C. Wood of the University of Pennsylvania contributes an interesting lecture on "Cold as an Antipyretic." Besides very practical suggestions as to the use of the various hydrotherapeutic remedies, there is a special section on "Air Baths." Professor Wood says: "Sometimes when cold-water baths are not to be had cold air becomes of great value for the reduction of temperature. The method at least in the winter time is of very simple application; the patient is covered with nothing but a thin sheet and the windows of the sick room widely opened until the temperature of the room has fallen sufficiently low. This cold-air treatment may be boldly employed, for patients with high temperatures cannot take cold. The thermometer must be the guide in the matter, and the patient's temperature must not be allowed to come down to the normal for it is to be remembered that the room will remain cool for some time after the windows are closed. The patient should not be exposed below the pelvis, and the legs and feet should be well protected. Any disposition to coldness of the feet is an indication for the local application of heat."

Professor Rosenheim's clinical lecture on "Chronic Constipation" is concluded, and contains some further very practical suggestions. This, for instance, seems novel on this side of the water at least. He insists on the plentiful consumption of fat for constipation, and suggests that when one form of fat is not well borne another may be; for instance, when butter disagrees things prepared in lard may not, or when both prove indigestible goose lard, or some of the vegetable table oils, may prove

palatable, produce no disagreeable symptoms, and accomplish the desired result.

Professor Eulenberg of Berlin has a very suggestive contribution on the "Present Position of the Treatment of Tabes," while Professor Fournier of Paris presents some very striking views as to the "Frequency of Cases of Unsuspected Syphilis."

From Professor Adolf Bagınsky of Berlin there is a clinical report that contains a clear discussion of certain subjects in pediatrics that have attracted a good deal of attention in recent years: "Laryngospasm, Eclampsia, and Tetany in Children; Their Connection with Rachitis, and with One Another." Rachitis is generally conceded by pediatrists abroad to be the common basis from which the three symptom complexes mentioned take their origin. Incidentally, the interesting question as to the influence of an enlarged thymus in causing laryngospasms in children, and sometimes causing sudden death is discussed. Among the causes of sudden death in children mentioned is the lymphatic condition for which Professor Bagınsky fails to see the necessity for creating a special rubric, as the cases included under it are only the outspoken examples of the scrofulous diathesis with which all physicians are familiar and for which a special name is not needed.

ALBUMINURIA AND BRIGHT'S DISEASE. By NESTOR TIRARD, M.D., F.R.C.P., Physician to King's College, London. London: Smith, Elder & Company, 1899.

THESE sentences from the author's introductory chapter supply a very good key-note to the contents of the book: "One of the chief difficultics connected with the term, Bright's disease, is that it has been so readily caught up by the non-medical world, and that it appears to be regarded among the laity as synonymous with albuminuria. This is much to be regretted as it frequently causes needless alarm and depression, when at some casual examination the presence of albumin in the urine has been detected."

The author might well have said that something of this same misapprehension still clings to medical minds, too. His book is eminently well planned to do away with this false impression for it is a thoroughly scientific and up-to-date discussion of albuminuria and its causes apart from Bright's disease, as well as of the various forms and phases of nephritis.

The chapter on renal or true albuminuria without definite structural change is especially complete. The discussion of the albuminuria that occurs after muscular exercise, of the albuminuria of hematogenous origin which has been noted in anemic states, especially in severe chlorosis, and of neurotic and febrile albuminuria, shows that the author has most conscientiously consulted the authorities on the subject and gleaned from the copious literature of nephritic and urinary conditions whatever is of interest and importance. The treatment of the subject of albuminuria seems especially to be commended inasmuch as a good deal of weight is laid on the opinion that physiological albuminuria is extremely rare, and that it should only be diagnosed when absolutely every possible pathological condition of the kidneys can be excluded. Dr. Tirard thinks it better to be over-cautious than to lull the patients into a false sense of security by the diagnosis of physiological albuminuria, albuminuria of adolescence and the like. Many of these subjects later develop true nephritis.

In the chapters on nephritis are found excellent reviews of recent opinions with regard to congestion of the kidney, to uremia, with a complete discussion of late suggestions as to its etiology, and also the interesting question of the association of albuminuria and glycosuria which has been noted so often by recent observers, especially in severe cases of diabetes. The accompanying albuminuria makes the prognosis of these cases even worse than when severe diabetes alone exists.

LES RAYONS DE ROENTGEN ET LE DIAGNOSTIC DE LA TUBERCULOSE. Par A. BECLERE, Medicin de l'Hôpital Saint Antoine. Paris: J. B. Baillière et Fils, 1899.

HALF of this work is devoted to a historical sketch of the subject of X-rays with a comparison of the merits of radioscopy and radiography. The author believes the former superior for the study of intrathoracic lesions in which the finer distinctions of shadows are lost in skiagraphs. For a subject yet in its inlancy the author takes a most optimistic view of the efficiency of the X-rays in disclosing incipient tubercular affections of the lung. The nine skiagrams included are illustrative of the supposed value of skiascopy.

ESSAYS FOR STUDENTS. By STEPHEN PAGET, F.R.C.S., Surgeon to the West London Hospital; Surgeon to the Ear and Throat Department of the Middlesex Hospital. New York: Wm. Wood & Co., 1899.

IN a charming colloquial fashion the author has recorded for students actual experiences on commonplace topics: strangulated hernia, cancer of the breast, some run-over cases, and elements of aural surgery. By the perusal of these essays the student will learn how to elicit the unbiased history of any case. These notes are free from any coloring or verbosity; yet the subjects are critically treated, and the same thoughtfulness is applied to the operative advice which is thoroughly abreast of progressive surgery. We hope that the success of this volume will impel its author to venture on another on the same lines.

LES REGENERATIONS D'ORGANES. Par le DR. PAUL CARNOT, Docteur des Sciences, Ancien Interne des Hôpitaux de Paris. Paris: J. B. Baillière et Fils, 1899.

THIS small compendium is a compilation of data bearing on the powers of regeneration in lower and higher animal life. In the first chapter regeneration is handled from the physiological, pathological, and traumatic standpoints, and these facts elucidated by comparison with zoological and emoryological phenomena together with the biomechanical forces at play in influencing ontogeny and phylogeny. Under the heading, "Regeneration of Structures Derived from Mesodermic Layer and Epidermic Layer," the practical feature of the regeneration of the in-

dividual organs is discussed. The author concludes that for vertebrates and man regeneration of function is of paramount importance to form; *i.e.*, that the conservation of function exacts the conservation of form which in many organs is assured by a diffuse hyperplasia of the entire organ in lieu of a local regeneration.

SAUNDERS' MEDICAL HAND-ATLASES. ATLAS OF DISEASES OF THE SKIN, Including an Epitome of Pathology and Treatment. By PROFESSOR DR. FRANZ MRACEK of Vienna. Authorized Translation. Edited by Henry W. Stelwagon, M.D., Clinical Professor of Dermatology in Jefferson Medical College, Philadelphia. With 63 colored plates and 39 full-page half-tone illustrations. Philadelphia: W. B. Saunders, 1899.

THE majority of medical schools in this country give but slight prominence in their curricula to the study of skin diseases, and as a result many general practitioners experience no little difficulty in formulating a correct diagnosis and instituting proper treatment in these conditions. Elaborate treatises have appeared from time to time but comparatively few have fulfiled the requirements of any save specialists in this particular branch of work.

No such criticism can be brought forward against the book under discussion. The first 191 pages are devoted to descriptions of the various skin lesions and their treatment, and the balance of the book to 104 full-page colored plates and half-tone cuts. Each illustration is drawn from life, and is accompanied by a clear and concise history of the disease in the patient whose case is pictured. A cross reference between the text and an illustration and history referring to the same disease at once simplifies the matter of diagnosis and clearly defines methods of treatment and the results which may be expected.

The translator's work has been well done and the editor's bracketed comments, while not numerous, assist in the elucidation of the text. The colored plates are masterpieces in their way, and the book-making in its entirety reflects great credit on the publisher.

SAUNDERS' MEDICAL HAND-ATLASES. ATLAS OF THE EXTERNAL DISEASES OF THE EYE, Including a Brief Treatise on the Pathology and Treatment. By PROFESSOR DR. O. HAAB of ZURICH. Authorized Translation from the German. Edited by G. E. DE SCHWEINITZ, M.D. With 76 colored plates and 6 engravings. Philadelphia: W. B. Saunders, 1899.

THIS is the American edition of Lehman's well-known series of hand atlases, and this number, on the External Diseases of the Eye, has been highly praised as a very practical presentation of the subject for the general practitioner rather than the specialist. The colored plates are very well done, and reproduce the pathological conditions with great accuracy as regards color and relations. The translation has been well done, and the practical touch of the experienced editor's hand can be noted in places, making the German text more suited to American practice. For stye, for instance, the German text writer suggests active poulticing with linseed meal to alleviate suffering, and shorten the process by bringing the abscess to the point of spontaneous evacuation or incision. The American editor suggests that repeatedly applied compresses soaked in hot carbolized solution, or in hot water containing thirty-three per cent. of fluid extract of hamamelis, is preferable. Then the remark: "The conjunctival hyperemia induced by eye-strain is a constant cause of chalazia and hordeola, therefore the necessity for correcting the refraction of the eye if it is anomalous," is just the added touch necessary to complete the clinical consideration of this very practical subject, but one which a German ophthalmologist would be apt to neglect.

THERAPEUTIC HINTS.

A Combination of Ichthyol and Creasote.—The good effects obtained from the administration of each of these drugs in tubercular pulmonary affections decided HUGO GOLDMAN to use them in combination. He prescribes as follows, claiming excellent results:

℞	Creasoti } aa		ʒ ss
	Ichthyol }		
	Glycerini		ʒ i
	Aq. menth. piper.		ʒ iiss.

M. Sig. Twenty to 30 drops in wine or lemonade three times a day after meals. For children and weakly individuals the dose is 10 to 20 drops.

For Squamous Blepharitis.—This occurs frequently in connection with seborrhea of the scalp, and gives rise to small crusts at the ciliary border of the eyelid. A sulphur ointment serves as the most effective means of cure, but is apt to cause a burning sensation and lachrimation by entering the conjunctival sac. TERRIEN advises, therefore, a weak preparation such as the following:

℞	Sulphuris præcip.		gr. iii
	Vaselini pur.		ʒ v.

M. Ft. unguentum. Sig. External use.

Solution for Fetidity of the Mouth.—

℞	Camphoræ		gr. lxxx
	Ac. salicylici } aa		ʒ iiss
	Ol. anisi }		
	Pulv. benzoini } aa		ʒ v
	Calcis chloratæ }		
	Glycerini		℥ vi
	Spiriti (forty per cent.)		ʒ x.

M. Sig. Mouth wash. Keep in dark bottle. One teaspoonful in a glass of water.

For Favus.—

℞	Potassii carbonat.		ʒ i
	Sulphuris sublim.		ʒ ss
	Tinct. iodi } aa		ʒ iss
	Picis liq. }		
	Adipis		ʒ iii.

M. Ft. unguentum. Sig. External use.

A thin layer of the ointment is spread on gauze and applied to diseased areas, being renewed daily. The slight dermatitis which may result is overcome by Lassar paste.—*Pirogoff.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, JULY 22, 1899. NO. 4.

ORIGINAL ARTICLES.

THE SERUM-TREATMENT AND ITS RESULTS.[1]

BY HERMANN M. BIGGS, M.D.,
OF NEW YORK.

AMONG the remarkable developments in medicine during the last ten years none has been more important in its practical value, nor more revolutionary in its effect on therapeutic possibilities and conceptions than the discoveries in serum-therapy. These discoveries have aroused the hope of the ultimate possibility of the production of artificial immunity to each one of the general infectious diseases of animals and man by the administration of innocuous or almost innocuous substances of bacterial origin, and there has apparently been placed almost within our grasp means for the specific treatment of many of these diseases.

The hopes earlier aroused in the minds of a few of the most enthusiastic workers in bacteriology have been more than realized in respect to diphtheria, and their most extravagant predictions have been actually exceeded by the results. The control of this disease, one of the most dreaded and fatal of diseases in modern times, has been rendered easily possible. The problems concerning diphtheria alone, however, of all the numerous and complex ones presented in bacteriologic therapy, have been completely solved so far as the practical aspects are concerned; but important contributions have been made to the solution of many others. In the study of each of these infectious diseases there are many unknown and variable factors whose determination requires most patient and painstaking investigation by methods newly worked out along new lines.

A full consideration of the present status of the serum-treatment involves the study of a large number of diseases, including diphtheria, typhoid fever, tetanus, pneumonia, streptococcus infections, cholera, yellow fever, tuberculosis, plague, leprosy, snake-venom, rinderpest, anthrax, rabies, and several other diseases of animals. The mere mention of this list shows the far-reaching effect of the epoch-making discoveries in relation to diphtheria and tetanus. Satisfactory practical results have not thus far been obtained in most of these diseases, but something has been accomplished experimentally in all, and the scientific observations have definite value as they assist in the solution of other problems.

It was my privilege to present before the Academy in April, 1895, a paper on the antitoxin treatment of diphtheria, then in its infancy, and the results obtained from its then limited use by the Department of Health of New York City. That paper called forth violent opposition. At that time the supporters of and believers in the treatment were few in number. The majority of the profession were waiting for more information and more evidence. The past four years have supplied this in amount and character sufficiently convincing to compel the acquiescence of every intelligence, whatever may have been the previous prejudice.

I desire first to consider rather carefully the results obtained in the serum-treatment of diphtheria, primarily in this city, and then, briefly, the results in some other great cities of the world.

A report of the results of the treatment of diphtheria with antitoxic serum (not including the hospitals) under the supervision of the Department of Health of New York City, covering the period from its inauguration, January 1, 1895, to October 1, 1896, was published in the MEDICAL NEWS in the issues for December 12, 19, and 26, 1896. The present report is intended to complete the data up to January 1, 1899. A summary of the cases previously recorded is also included.

It may be said in an explanatory way that on January 1, 1895, the Department of Health of New York City commenced the use of diphtheria antitoxin prepared in its bacteriologic laboratories. The supply of foreign preparations at this time was limited; only a few vials of reliable antitoxin of any grade could be obtained (none was then being produced in this country) and the prices were exorbitant, averaging about 80 cents per 100 antitoxin units (Behring's standard), or from $8 to $12 for a dose of from one-third to one-half the size of that now generally employed. All of the preparations of serum then in use were of a low grade, and their use has long since been entirely discontinued in this city.

The serum originally prepared in the laboratories of the Department of Health was first employed in the hospitals, but as soon as a sufficient quantity was at hand, arrangements were made for its adminis-

[1] Read before the New York Academy of Medicine, March, 1899.

tration without charge (at the request of the attending physician) by inspectors detailed for this purpose to any case of diphtheria occurring in the city, and a little later arrangements were made for the free distribution of antitoxin to all public institutions and for use among those too poor to pay for the remedy; and, finally, by a special act of the Legislature, the department was authorized to sell any surplus product, the proceeds from these sales to be deposited with the Comptroller as a special antitoxin fund, subject to requisition by the Department of Health for the further production of diphtheria antitoxin, or other antitoxins, and for the expenses connected with the treatment of cases of diphtheria among the poor.

During the first period, ending October 1, 1896, 1252 cases of true diphtheria were treated by the inspectors detailed for this purpose, with 198 deaths, giving a mortality of 15.8 per cent. Of these 80 were moribund at the time of the first injection, or died within twenty-four hours after the first injection of antitoxin; deducting these, the mortality was 10 per cent. From October 1, 1896, to January 1, 1898, 1195 cases were treated, with 163 deaths, giving a mortality of 13.6 per cent. Of these 71 were moribund; deducting these, the mortality in the second series was 8.1 per cent. From January 1, 1898, to January 1, 1899, there were treated 626 cases, with 68 deaths, giving a mortality of 10.8 per cent.; deducting 21 moribund cases, the mortality was 7.7 per cent. During the whole period from January 1, 1895, to January 1, 1899, there have been treated in all 3073 cases, with 429 deaths, giving an average mortality of 13.9 per cent.; deducting 172 moribund cases, there remains a total of 2901 cases, with 257 deaths, a mortality of 8.8 per cent. In addition to these 455 cases were treated and have been excluded from the table, either because they showed on bacteriological examination no Löffler bacilli, and were not regarded as cases of true diphtheria, or were found to be cases of true diphtheria, and were transferred to the Willard Parker Hospital, and therefore passed from observation of the inspectors.

The cases referred to do not include any of those treated in the various institutions of the city or in the hospitals of the Department, and were, as a rule, among the very poorest classes in the tenement-house districts. They have, generally speaking, been under the most unfavorable conditions; have been severe cases, or regarded by the physicians in attendance as hopeless cases, and have often come under observation late in the course of the disease. In a large proportion of the whole number there was practically no other treatment besides the administration of antitoxin. In some cases, strychnin, whisky, and other remedies were also given, but in many instances the physicians in attendance discontinued their visits after referring the cases to the Department of Health for the administration of antitoxin, as the families of the patients were too poor to pay for their attendance.

There has been from the beginning a continuous and marked improvement in the results obtained, in consequence, it is believed, of the increased experience in the use of this agent by the medical inspectors appointed to this duty, the earlier application of the treatment, the constant improvement in the character of the serum, and the larger dosage employed. During the first year the mortality among these cases was 17.9 per cent., and during the last twelve months it was 10.8 per cent., moribund cases included.

For the execution of the plan adopted for the free administration of antitoxin among the poor, the city was divided into districts, each district being placed in charge of a medical inspector, who is always on duty and liable to be called at any hour during the day or night. Requests for the administration of antitoxin are received at the office of the Department of Health from the attending physician, and immediately referred by police telegram or by telephone to the inspector in charge of the district in which the case occurs.

In a large majority of all cases treated only one injection of antitoxin was administered; in all severe cases since the end of the first year of the work the initial dose was large, varying from 2000 to 4000 units, experience showing that the best results were obtained from large initial doses, and the tendency has been to constantly increase the size of this dose. This experience is in direct confirmation of the conclusions reached in the experimental investigations on animals. As a rule, the patients were seen a second time at the end of 24 hours, and when it was considered necessary a second injection was then administered. They were afterward seen at intervals as seemed necessary, until the disease had terminated either in complete convalescence or death.

The serum employed has been generally of high grade, varying from 300 to 800 or more units in each c.c. Better results have been obtained with the use of high-grade preparations and with larger doses of antitoxin. In the earlier months, when large quantities of serum were administered,—the serum containing proportionately less antitoxin,—rashes were of frequent occurrence, and their frequency varied with different preparations obtained from different animals; but no reliable data as to the

percentage of cases in which they appeared are at command. There has been a marked diminution in the frequency with which rashes have occurred and in their severity since the use of the higher grade preparations, in which smaller doses of serum are employed. No case has come under observation in which any permanent injury could be properly attributed to the remedy.

The data as regards complications are incomplete, as in the class of patients treated—often the most ignorant of the foreign-born population under the conditions existing in the poorest tenement-houses—careful observations could not be made. In many instances, serious complications independent of diphtheria, such as scarlet fever, measles, and whooping-cough, acted as contributing or determining causes of death in the fatal cases—all such have been included. In all, with few exceptions, in which the clinical features were unmistakable, the clinical diagnosis was confirmed by bacteriological examination. In a few instances the result of the bacteriological examination was indecisive, while the case was evidently diphtheria, and these have been included. In others, bacteriological examinations showed clearly that the cases were false diphtheria, and all such have been excluded from the list. The usual practice has been, when a case was seen for the first time by the inspector (at the request of the attending physician), to administer an injection of antitoxin, if the disease seemed clinically to be diphtheria, and at the same time to make a culture from the throat for bacteriological examination, if a culture had not been previously made. The course subsequently pursued in each instance depended upon the results of the bacteriological examination.

When cases of diphtheria were seen in families in which there were other children, who had been exposed to the disease and when the parents would allow it, an immunizing injection was administered to each of the children and often to the adult members of the family. In most instances, recently, after immunizing injections have been administered, no attempt has been made to separate the case of diphtheria from the well members of the family, as experience showed that such separation was unnecessary. Altogether 5108 persons in tenement-houses have been immunized, from 200 to 800 antitoxin units being administered to each person. These persons were members of nearly 2000 different families, and among them there occurred within 24 hours 26 cases of diphtheria, of which one only—a patient with croup—died. Undoubtedly in these persons, the disease was already developing at the time of the administration of the antitoxin, and the amount administered—an immunizing dose— was not sufficient to completely check the disease. After 24 hours, and within 30 days, 23 cases occurred. All of these patients recovered with the exception of 1, who developed *scarlatina* and *diphtheria* on the *second* day after the immunization. This child died. After 30 days, so far as is known, 7 cases occurred, of whom two died, one on the 36th, and one on the 55th day, respectively, after the administration of the immunizing dose. In other words, in 5108 persons immunized in about 2000 families 4 deaths subsequently occurred—one from croup, which developed within 24 hours; one from scarlatina and diphtheria, which developed on the second day, and 2 from diphtheria, which developed, 1 on the 36th, and the other on the 55th day of the disease. The data regarding the occurrence of cases of diphtheria among those immunized after 30 days are probably not complete, as many of these cases were not subsequently followed.

The experience of the inspectors with immunization is quite in accord with that obtained from the immunization of children in various institutions in this city and elsewhere, and indicates that the protective influence of the immunizing injections can generally be depended upon to last from three to four weeks, although in many cases the period is apparently longer. The results have been better since somewhat larger doses have been administered. With the high-grade preparations of antitoxin now employed the amount of serum required for an immunizing injection is so small—varying from 5 to 15 minims according to the age of the patient and the strength of the preparation—as to be entirely unobjectionable. In the earlier work, when young and feeble infants were immunized, some restlessness, accompanied by more or less pyrexia, occurred in many cases during the first twenty-four hours, and not infrequently a rash appeared later.

The accompanying tables, I., II., III., IV., and V., give more complete data concerning the cases of diphtheria treated with antitoxin by the Department of Health Inspectors, January 1, 1895, to January 1, 1899.

I have also prepared a table showing the absolute number of deaths annually and the death-rates per 100,000 population from diphtheria and croup in several of the large cities of the world, notably, Paris, Berlin, and New York, where diphtheria antitoxic serum has been generally employed, which gives most striking testimony of the value of this remedy. In each of these great cities the death-rate has been reduced to less than one-half of the lowest death-rate recorded previous to 1894. In Paris the rate is about 30 per cent., and in New York about 29 per cent. of the rate for 1894. In

1894 there were 2870 deaths from diphtheria and croup in New York City; pneumonia and tuberculosis only exceeding diphtheria and croup in the number of deaths caused. In 1898 the deaths were 923; the number of cases of diphtheria and croup reported in 1898 is also below the number for any year since 1893, and the case fatality is lower, being 12.2 per cent., as contrasted with 40 per cent. for 1892, 36.4 for 1893, and 29.7 for 1894. The diminution in the actual number of deaths and the diminution in the death-rate per 100,000 population since 1894 has been greater in New York City than in any other great city in the world.

These data are in striking contrast with the conditions in London, where diphtheria antitoxic serum has been used to a very limited extent outside of the hospitals of the Metropolitan Asylums Board. While there has been some reduction in the number of deaths from diphtheria in London since 1893, it is inconsiderable. The present mortality is still greater than that in London previous to 1894, and is in great contrast with the reductions which have taken place in other great cities. Previous to 1894 there had been a very great increase in London in the notifications of diphtheria and croup and the deaths from these diseases. In 1893 there were the greatest number of deaths ever recorded—3484. Cobbett in a recent article has carefully analyzed the conditions, and has ascribed the difference in the results obtained with reference to this disease in London and on the Continent to several causes: 1st, the increasing prevalence of the disease in London in recent years; 2d, the severe type prevailing; 3d, the poor quality of the serum; 4th, the much less extensive use of the serum.

Dr. Goodall, however, commenting on the statistics given by Cobbett and the results of his calculations, gives the following table showing the percentage mortality of all cases of diphtheria in London City and in the Metropolitan Asylums Board hospitals since 1892:

	1892	1893	1894	1895	1896	1897
Fatality per cent. of all notified cases	23.8	24.5	24.7	21.2	19.4	17.4
Fatality per cent. of all notified cases admitted to M. A. B. Hospitals	24.8	27.1	25.5	18.3	17.7	14.9
Fatality per cent. of all notified cases not admitted to M. A. B. Hospitals	21.5	23.7	24.5	23.3	21.3	20.1
Percentage of notified cases admitted to M. A. B. Hospitals	31.1	24.5	38.8	41.5	39.9	51.4

"This table," Goodall remarks, "shows, but more emphatically than Cobbett's tables, that whereas the fatality of hospital-treated cases was up to 1894 greater than that for the whole of London, since that year the reverse has been the case. It also shows that the improvement in the fatality-rate is more marked in the hospital cases than in those not admitted to hospitals. It further shows that there has been some improvement in the fatality of cases not admitted to hospital. It is very uncertain that the improvement in these last cases is due to the use of antitoxin. Doubtless some cases are admitted to the general hospitals and are treated in them with serum. Possibly the improvement may be due to this fact; but, if so, it only emphasizes Cobbett's statement, to the effect that outside of hospitals the antitoxin treatment is little employed." Goodall says that from his own experience he knows this to be the case.

A reference should also be made to the remarkable results which have attended the use of diphtheria antitoxic serum in Chicago under the supervision of the Department of Health. During the month of November, 1898, according to the reports of the Department of Health for December, 1898, 168 cases of diphtheria were reported to the Department and examined bacteriologically. Of these 98, found to be true diphtheria, were treated with antitoxin. Four cases remaining over from the preceding month were also under treatment. Of the 102 cases 97 are reported as having recovered, 2 remained under treatment, and 3 died, giving a mortality of three per cent. in completed cases. Ten of the patients treated were intubated, so that diphtheria during the month was not of a mild form. Two of the 3 deaths were intubation cases, and all 3 of the fatal cases were first seen by the inspectors of the Department later than the fourth day. To this report for the month are appended the following details of the results obtained in Chicago since the original introduction of the antitoxin treatment by the Department in October, 1895: During the succeeding twenty-six months to date, the physicians of the Department have examined 5739 cases of suspected diphtheria. Of these 3956 were found to be true and all but 134 (treated by family physicians) were treated by the Department. Out of the 3822 cases thus treated 3763 recovered and 259 died, a mortality of 6.7 per cent. Before the introduction of antitoxin the mortality-rate of diphtheria in Chicago was thirty-five per cent. "At this rate there would have been 1337 deaths among the number actually attacked instead of 259—a clear gain of 1100 lives in a space of scarcely more than two years. Besides this there were 3633 persons immunized in families exposed to infection. Only 30 out of this number were subsequently attacked by the disease; they all

had mild attacks and recovered." It is estimated by the Chicago Board of Health that in twenty-six months there has been a saving to the City of Chicago, thanks to diphtheria antitoxin, of 1713 lives.

A consideration of the deaths and the mortality per cent. in the hospitals of Paris, Berlin, and London shows the same facts as the rates for the entire cities, the number of deaths and mortality per cent. in Paris and Berlin having been reduced to a third or less, while in London the reduction has been far less and the number of cases treated has nearly doubled.

The large reduction in the number of cases of diphtheria in New York in the last year as compared with the six years immediately preceding I believe to be due to several factors: First, the general use of antitoxin and the consequent diminished severity of the cases occurring. A severe case of diphtheria is far more likely to be a source of infection to others than a mild one, especially in the tenement-house districts, because the discharges from severe cases are so much more abundant, and the difficulty in destroying them is so much greater. Second, the use of antitoxin as an immunizing agent has largely decreased the number of secondary cases. Nearly 2000 persons, mostly children (who had been exposed to diphtheria), were immunized during the last year by the Department of Health, and the remedy has also been largely used for this purpose by private physicians. Third, the introduction by the Department of Health of the medical inspection of schools, and the greater care in the inspection of cases in tenement-house districts have both contributed to the result.

But not only has there been a great decrease in the deaths in the great cities, but the same has been found to be true in the smaller cities of France and Germany, where this subject has been carefully investigated. In 266 German towns, with a population of over 15,000, for nine years preceding 1895 the average deaths per 10,000 inhabitants was 106. In 1895 this fell to 53, in 1896 to 43, and in 1897 to 35, or less than one-third of the average for nine years previous to 1894.

Sidney Martin of London, in concluding a careful report on the results obtained from the use of antitoxic serum in the University College Hospital, London, in which the death-rate is shown to have diminished from 37 and 39 per cent., respectively, in 1893 and 1894 to 17 per cent. in 1897, and the death-rate in operative laryngeal cases from 65 per cent. to 26 per cent., says "the great reduction, both in the total and in the tracheotomy mortality can only be due to the treatment with antitoxic serum, for the examination of the cases revealed no other factor capable of producing this result." Martin recommends the use of very large initial doses, not less than 6000 normal units, and insists that it should be administered as soon as a suspicious throat is seen, without waiting for a bacteriological diagnosis of the disease. He also gives a table to show the diminished severity of the disease, and the shorter duration of the pyrexia when antitoxin is employed.

The conclusions of the Committee of the American Pediatric Society in reporting an investigation of the antitoxin treatment of laryngeal diphtheria in private practice need only be referred to. 1704 cases of laryngeal diphtheria were included in this report as treated with antitoxin, of which 668 were operated upon. Of these 182 died, giving a mortality of 27.2 per cent. Before the use of antitoxin it was estimated that 90 per cent. of the cases of laryngeal diphtheria required operation, whereas now only 39 per cent. require it. Previously 27 per cent. approximately represented the recoveries, while now 27 per cent. represents the mortality, exactly reversing the figures; in other words, before the use of antitoxin 27 per cent. recovered, while now 73 per cent. recover.

I desire to say a few words further in regard to the use of diphtheria antitoxic serum for immunization against diphtheria, for while the remedy is now universally employed throughout the world in the treatment of this disease it is much less generally employed as an immunizing agent. It was early employed in New York City, and has been more generally used here for this purpose than anywhere else in the world. The results here, however, have had ample confirmation in Europe. In the children's department of the Charitè Hospital, Berlin, where formerly patients frequently contracted the disease, owing to the want of efficient isolation, the systematic use of immunizing injections was introduced three years ago. Since January, 1896, patients have even received injections every three weeks, as it was found that the resulting immunity could not be depended upon for a much longer period than this. The result has been that no child thus immunized has contracted the disease; this fact seems more remarkable because it was found that the diphtheria bacilli were present in the throats of nearly one-quarter of the children who were examined during a period of 5 months.

In order to ascertain whether the resulting immunity was due to the injections, or to some other influence, the injections were stopped in October, 1897. Shortly afterward, namely, early in November, a child three and a half years of age, suffering from Bright's disease, developed laryngeal diphtheria and died. A little later two other children in the same ward were attacked with typical

pharyngeal diphtheria, and a fourth child, who had been admitted for measles early in October, developed croup. These last three patients recovered after the injection of diphtheria antitoxin. After this experience the immunizing injections were resumed, and no further cases of diphtheria have occurred. The experiences previously reported in institutions in this city give exactly parallel results.

I shall only refer the reader to the accompanying tables for the results in the laryngeal cases treated by the inspectors of this city, although in many respects these afford the best test of the efficacy of the antitoxin treatment.

From the statistics presented it is apparent that the mortality from diphtheria and croup, which was so markedly reduced on the introduction and in consequence of the use of antitoxin, has continued to decrease in proportion as the remedy has been more generally employed. It would be useless at this time to multiply statistics on this subject, which on the largest scale, and from the most diverse sources have given affirmative evidence of the value of antitoxic serum in the treatment of diphtheria. It is not easy to understand the mental attitude of those who still continue to oppose the antitoxin treatment of diphtheria in the face of the enormous mass of evidence in its favor. Whatever may be said of statistics in general, no practitioner who examines impartially the reports published by the New York City Department of Health, and reads the wholly unprejudiced and impersonal collective investigations instituted by the American Pediatric Society, by the Berlin Society for Internal Medicine, and the Kaiserliches Gesundheitsamt, and the exhaustive and elaborate statistical studies issued by the medical superintendents of the hospitals of the London Asylums Board can fail to be convinced of the specific value of this remedy.

TABLE. I.

Cases of diphtheria treated with antitoxin by the Department of Health, January 1, 1898, to January 1, 1899, with a summary of cases treated, January 1, 1895, to January 1, 1899.

Total cases of true diphtheria injected with antitoxin by the Medical Inspectors of the Department of Health, showing the number of cases injected and the mortality percentage.

TABLE V.

Immunization with antitoxin by the Department of Health Inspectors, January 1, 1898, to January 1, 1899, with summary of cases immunized, January 1, 1895, to January 1, 1899.

Table of cases immunized with injections of antitoxin in families where diphtheria had occurred, showing the number of cases immunized, the number of cases which occurred after thirty days and within twenty-four hours after injection, and those which occurred within thirty days after injection.

No. of Cases Immunized.	No. of Cases of Diphtheria within 30 days after Injection.	No. of Cases of Diphtheria within 24 hours and after 30 days after Injection.
Jan. 1, 1898, to Jan. 1, 1899. 1,408 Cases.	1 on the 7th day, moderately severe, recovered. 1 on the 3d day, mild, recovered. 1, no day stated, mild, recovered.	
Jan. 1, 1895, to Oct. 1, 1896. 1,207 Cases.	1 on the 7th day, 1 on the 10th day, 5 on the 19th day, 1 on the 23d day, 1 on the 30th day, Mild, recovered. 1 on the 5th day, severe, recovered. 1 scarlet fever and diphtheria, died on the 2nd day.	
Oct. 1, 1896, to Jan. 1, 1898. 2,493 Cases.	2, no day stated, 2 on the 7th day, 2 on the 8th day, 1 on the 9th day, 1 on the 12th day, Mild, recovered. 1 on the 30th day, moderately severe, recovered.	

TABLE V.—*Continued.*

Jan. 1, 1895, to Jan. 1, 1899. 5,108 Cases.	19 mild, recovered. 3 severe, recovered. 1 scarlet fever and diphtheria, died on the 2d day.	Within 24 hours. 15 mild, recovered. 10 severe, recovered. 1 croup, died. After 30 days. 3 mild, recovered. 4 severe, recovered. 2 septic, died on 55th and 38th day, respectively

NOTE TO TABLE V.: There were, in all, 1538 families in which one or more cases of diphtheria had occurred previous to immunization. Out of a total of 5108 cases immunized during the four years, 1895 to 1899, only 3 deaths from diphtheria occurred, 1 developing on the second day after immunization of scarlatina and diphtheria, and 2 septic cases on the fifty-fifth and thirty-eighth days, respectively, after immunization; 25 cases of diphtheria which occurred within twenty-four hours, 22 cases within thirty days, and 7 cases after thirty days after injection, in all 54 cases, recovered.

On October 1, 1895, arrangements were made to enable physicians to obtain supplies of antitoxin free for use among patients too poor to pay for the remedy, on condition that reports of the cases thus treated should be furnished to the Department of Health. Druggists acting as agents for the sale of antitoxin were instructed to furnish the remedy free to any physician upon his statement that the patient for whom it was intended was not in circumstances to pay for it. A blank was furnished upon which the history of the case could be filled out by the attending physician upon the termination of the case, either by death or recovery. This arrange-

ment, not very generally known or utilized by physicians at first, has come more and more into use until now a large number of cases of diphtheria are treated by physicians with antitoxin furnished free to poor patients.

TABLE VI.

Cases of diphtheria treated by physicians with free antitoxin, collated from the reports of the attending physicians, January 1, 1898, to January 1, 1899, with summary of cases treated, October 1, 1895, to January 1, 1899.

	Cases.	Deaths.	Mortality Per cent.
Jan. 1, 1898, to Jan. 1, 1899	868	138	15.9
Moribund cases deducted.	60	....	....
Remaining	808	78	9.6
TOTAL CASES.			
Oct. 1, 1895, to Jan. 1, 1899	2,112	373	17.6
Moribund cases deducted.	143	....	....
Remaining	1,969	230	11.7

NOTE TO TABLE VI.: From January 1, 1898, to January 1, 1899, there were treated with free antitoxin 868 cases, with 138 deaths, giving a mortality of 15.9 per cent.; of these 60 were moribund at the time of or died within twenty-four hours after the first injection; deducting these the mortality was 9.6 per cent. Of the total cases treated with free antitoxin from October 1, 1895, to January 1, 1899, *viz.*, 2112, 373 died, giving a mortality for the three years of 17.6 per cent. Deducting 143 moribund cases the mortality was 11.7 per cent.

Altogether 2511 cases of suspected diphtheria were injected with free antitoxin, October 1, 1895, to January 1, 1899, but 399 of these are excluded from the statistics, either because on culture examination no diphtheria bacilli were found, or because they were transferred to the Willard Parker Hospital; and thus passed from observation, or because the data furnished were insufficient for tabulation.

Of the 2112 cases included in the statistics, 1458 were bacteriologically confirmed to be true diphtheria; of these 180 cases died, or 12.3 per cent. Of the 654 cases not confirmed by bacteriological examination, but proving to be clinically undoubted diphtheria, 173 died, or 26.5 per cent. Many of these were moribund at the time of the first injection.

TABLE VII.

Cases of laryngeal diphtheria treated by physicians with free antitoxin, January 1, 1898, to January 1, 1899, with summary of cases, October 1, 1895, to January 1, 1899.

TABLE VIII.

Absolute annual deaths and death-rates for 100,000 population from diphtheria and croup in Paris, Berlin, and New York (Manhattan and Bronx) from 1886 to 1898 inclusive.

	Paris.		Berlin.		New York.	
	Absolute Deaths.	Death rate per 100,000 population.	Absolute Deaths.	Death rate per 100,000 population.	Absolute Deaths.	Death rate per 100,000 population.
1886	1,524	73.2	1,662	125.7	2,695	187.5
1887	1,564	76.9	1,392	100.7	3,056	206.6
1888	1,718	83.7	1,195	76.1	2,553	167.7
1889	1,706	79.9	1,210	85.6	2,291	146.2
1890	1,639	77.5	1,601	102.0	1,783	110.6
1891	1,363	63.0	1,342	67.5	1,970	118.7
1892	1,398	63.6	1,637	92.5	2,106	123.3
1893	1,262	51.4	1,416	100.8	2,558	145.5
1894	993	40.7	1,321	86.7	2,870	158.4
1895	435	17.8	987	59.2	1,976	105.2
1896	444	17.6	559	30.4	1,763	91.2
1897	351	13.8	546	31.5	1,590	79.9
1898	301	12.0	652	32.4	923	45.1

NOTE: The figures for 1897 and the first half of 1898 in Paris and Berlin are taken from the monthly reports, while the latter half of 1898 is estimated from the weekly reports. The rest of the data are taken from the annual reports.

It will be seen from an examination of this table that the average number of deaths from diphtheria and croup in Paris and Berlin for the preantitoxin period (1886 to 1895) was 1463 and 1419 respectively, whereas for the antitoxin period (1895 to 1899) it was 383 and 626, or less than one-half. In New York City antitoxin has not been so generally used as in the other two cities until the last year. But the average number of deaths from diphtheria and croup in New York from 1886 to 1895 was 2654, while from 1895 to 1899 it fell to 1563, and in 1898 it was only 923. The fall in the death-rate from this disease since the introduction of antitoxin is equally conspicuous, estimated per 100,000 of the population.

Diphtheria has always been much more prevalent in the great cities of this country, and especially New York, than in the capitals of Europe, and the death-rate per 100,000 of the population has always been and still remains much higher. The diminution in the death-rate, however, in 1898, as compared with 1894, is greater in New York than in either Paris or Berlin, or any great city of Europe. The case fatality, too, is as low or lower than that of any other great city. The great prevalence of the disease in New York is no doubt due to the great density of the population and the character of the housing of the tenement-house population, which is more favorable to the extension of infectious diseases than that of any great city of the world.

TABLE IX.

Diphtheria and croup in New York City from 1891 to 1898 inclusive, showing cases, deaths, and case fatality.

	Cases.			Deaths.			Case Fatality.

1898	7,213	380	7,593	788	135	923	10.9	12.2

NOTE: Previous to 1891 croup, not being classed as a contagious disease, was not reported to the Health Department. In January, 1895, the distribution and use of antitoxin produced by the New York Department of Health was begun, but antitoxin did not come into general use in the city until 1896.

TABLE X.

Cases, deaths, and mortality percentage of all cases of diphtheria in the hospitals of Paris, Berlin, and London from 1893 to 1898.

	PARIS HOSPITALS.			BERLIN HOSPITALS.			LONDON HOSPITALS.		
	Cases.	Deaths.	Mortality Per cent.	Cases.	Deaths.	Mortality Per cent.	Cases.	Deaths.	Mortality Per cent.
1893	1,882	968	51.4	2,450	951	38.8	2,848	865	30.3
1894	2,355	837	35.5	2,890	801	27.7	3,666	1,035	28.2
1895	2,664	363	13.6	3,061	484	15.8	3,685	820	22.2
1896	2,363	360	15.2	2,138	285	13.3	4,508	948	21.0
1897	1,683	253	15.0	1,937	263	13.5	5,673	987	17.4

NOTE: The statistics for 1898 have not been published in full, and are, therefore, omitted. Antitoxin was introduced into the hospitals of Paris and Berlin toward the end of 1894, but was not generally employed until 1895. In the hospitals of the Metropolitan Asylum Board of London antitoxin was not introduced until 1895.

(To be continued.)

LIGHT AND AIR IN THE TREATMENT OF CONSUMPTION IN COLORADO.[1]

BY CHARLES FOX GARDINER, M.D.,
OF COLORADO SPRINGS, COL.

IN the etiology of pulmonary tuberculosis one fact stands out more clearly and is proved more positively than any other, and that is the enormous influence such simple factors as light and fresh air have upon the development of this disease. In fact from the dawn of human history this influence has been noted,[2] and all human experience as well as scientific research have demonstrated that consumption is a disease of the indoor domestic animal, man included, and that when air and light are curtailed, then consumption begins to strike down those who from deficient lung power are least fitted to survive. Another fact now proved beyond question is that reversing the greatest predisposing cause (a lack of air and light), and supplying the air and light to excess, we have the most powerful weapon now known with which to fight and conquer this widespread and destructive disease. Even nutrition, important and powerful as it certainly is in treating the tubercular, must hold second place to light and air. I have seen hundreds of range cattle exposed to air and light dying of starvation and cold and never a case of tuberculosis among them; while, on the other hand, cattle from the same herd, sheltered, well fed and cared for, do occasionally develop the disease. It seems to me that, in the face of such strong evidence as we can now show as to the value of air and light in curing consumption (a remedy far more effectual than all other agents taken together), the average physician passes over them with scant notice, and the brief order to the patient, "Be out all you can," results in but a small daily dose of fresh air—a quantity entirely too limited for the result desired. That this is a mistake, and that the most efficient remedy we have for consumption should be used with care, system, and in heroic doses, is very clearly shown by the results obtained in the sanatoriums both in this country and abroad.[1]

When used as a cure the qualities of the air should be considered; these depend upon climatic conditions, and to state, as some men have, that, conditions being equal in other respects, climate is of little importance is not true or logical. As the dose and purity of a drug determine its favorable action upon the diseased condition it is intended to cure, so the dose and purity of the air and light, used as a cure, determine their efficient action in consumption. Any student of climatology knows that air and light differ materially in available dose and purity, even in narrow geographical limits, while a more extended view shows us climatic changes much more intense and radical. Air ought to be (1) pure—free from dust and germs;[2] (2) dry and thin—to favor chest expansion, to give greater supply of blood to the lungs and increased richness to the blood, and also to permit greater penetration of solar rays, thus limiting tubercular infection from others;[3] (3) cool—to act as a stimulant; (4) and with an excess of ozone and electricity.[4]

[2] *Tuberculosis and Altitude.* — In a recent work published in Mexico (*La Vie sur les Hauts Plateaux*), which won the Hodgkins' prize of the Smithsonian Institute, Herreta and Lope devote a chapter to the treatment of tuberculosis by altitude, noteworthy in many respects. They find that statistics show that not only in men but in lower animals tuberculosis is decreased in high regions. In 1885, out of 73,000 cattle killed in the general abattoir of the City of Mexico, only forty-five were tuberculous. This favorable effect they attribute to the higher solar illumination in high altitudes and the dryness and coolness of the atmosphere as working against the existence of microbes. The benefits of rarefied air in consumption are given by the authors from their experimental and other observations, as follows: (1) Lessening pressure increases the circulation of air in the lungs, dilates them and obliges torpid parts to functionate. (2) Lessening pressure determines a greater quantity of blood in the lungs. (3) Lessening pressure permits a uniform distribution of blood, regulates its circulation and combats congestion. (4) Lessening pressure diminishes intrapulmonary tension in general and particularly intravascular tension. (5) Augmentation of red and white globules. (6) Desiccation of mucous surfaces; the favoring of evaporation, besides experiments on animals, observations of actual cases of tuberculosis, treated by rarefied air, are reported by the authors. Of 13 patients thus treated only 1 lost weight, 1 remained stationary, and 11 notably increased, 1 increasing 300 grams in one day. In none, either healthy or tuberculous, were the alarming symptoms described by Paul Bert experienced.

[4] Braithwaite's "Retrospect of Medicine," p. 239, 1899.

Light should be sunshine, or directly diffused from it, and with as little cloudy or white light as possible. With these qualities of light and air, we have at our command the most powerful agents known for the cure or arrest of pulmonary phthisis, and these perfect atmospheric conditions are found only upon the dry, high plateaux of the world. Some of the qualities spoken of are found at the seashore, some in low elevations, as in a desert atmosphere; but for all the qualities mentioned in both light and air, altitude and dryness must be present. The effects of sunlight upon germ life are well-known to all, and recent observations have shown that a partial absence of light tends to, and even does, develop consumption, when the air supply and other conditions remain the same.[1] Then, too, the direct solar rays are now known to penetrate live tissue and exert their influence as germicides. Experiments by Koch, Downs, Blunt, Duclaux, Esmarch, and Arloing are cited by Abrams—all tending to show the power and penetration of solar rays, their effect as a stimulant of cellular life of plants and animals in health and disease, and their power as a cure. There is also good reason to believe that the solar rays pass through ordinary clothing and have a stimulating effect upon capillary circulation, and nerve endings.

A climate which has all the qualities of light and air that I have mentioned, ought to present ideal climatic conditions for the cure of consumption. In Colorado these climatic conditions do exist. Not only is there an average of fifty per cent. more sunshine every day in Colorado than in any State east of the Mississippi River, but the soil, temperature, and dryness of the air permit the pulmonary invalid to take advantage of these conditions. A simple experiment illustrates atmospheric light penetration in Colorado: expose several films in a camera (time exposure), and then under the same conditions in regard to films, time, sunlight, etc., expose the other half of the films at sea-level, or at the seashore, and the latter set of films will be found to be fogged from under exposure, the more dense air not allowing light to penetrate as easily as in Colorado. It is probably this property in the air of Colorado (dermithisity or thinness) that removes color so rapidly from all dyed fabrics, tans the exposed skin so easily, and allows the sun and diffused light to act so powerfully as a germicide. The practical point is to utilize this light and air in the best possible way for our patients in Colorado, or in all sections of the country having these climatic advantages.

To ascertain the time spent out of doors by the average invalid in Colorado Springs I have departed somewhat from the method of making meteorological tables, which show merely the number of days suitable for him to be out, and have compiled a list giving the time an average invalid actually spends in the open air. Meteorological tables, no matter how carefully compiled, give but a limited idea as to certain climatic details. Temperature is frequently misleading, as in Colorado the dry air allows an outdoor life at temperatures that would in a more humid climate be impossible or dangerous, while such climatic factors as dust are not noted in ordinary tables; and so on. This chart has been compiled from an average of observations taken during the time from December 16, 1898, to April 19, 1899. This was to make as severe a test as possible, as it is during these months we have in Colorado our most inclement weather. As last winter and spring were of unusual severity, in fact from all I can learn, the worst weather for any length of time of which we have a record, one can see that in this chart no flattering picture is drawn regarding our winter weather. By average invalid I mean those who are too ill to exercise by horseback-riding, cycling or golfing, or even walking, except very slowly, and yet are able to be up and about, and to spend considerable time out of doors, provided they are protected and can sit or lie down. The time spent out doors can be regulated to a fine point in a sanatorium, but I refer to invalids who are in their own homes, in hotels or boarding-houses. I tell these patients, as most doctors do, that they must be out all they possibly can. I specify the hours and arrange the details of shelter, etc., selecting the winter months, as that is the season when an open air life become so necessary to the pulmonary invalid, for he feels the cold and will instinctively choose the warm and often close air of a room, inhaling furnace gas, dust, and germs. In summer it is, on the contrary, an easy problem to induce patients to live an outdoor life; then all nature beckons to one, and even indoors the air is fairly pure by comparison, owing to the open doors and windows and the absence of artificial heat. I find that the average invalid spends outdoors daily about five hours, either on a piazza, driving, or at times walking a little. If the air and light are as important curative agents as I have stated, then five hours daily outdoors are not enough; we should aim at twenty-four hours. If we desire the best results we cannot afford to waste a single hour in fighting such a disease as tuberculosis. Few people realize the vast difference that exists between a so-called well-ventilated room and the open air; the former is enough to kill an Indian.[1]

[1] Robinson, "Climatology of Nudity," *Trans. Amer. Climatological Asso.*, p. 233, 1898.

[1] "Environment in Its Relation to the Progress of Bacterial Invasion in Tuberculosis," *Amer. Jour. of the Med. Sciences*, July,

The experience of one who has just returned to his ordinary habits from a life of several weeks spent entirely in the open air illustrates this. No matter how well ventilated the room in which he sleeps, it will seem close and a cold in the head is apt to result. A simple experiment seems to me to bear closely on this subject. Take a piece of fresh venison or any meat and hang half of it in a room protected by fly screens, hanging the other half on top of a pole in the open air in the sun; even if this is done in the months of July or August the meat outside will remain fresh for weeks, while the meat in the room will spoil in a day or two. This is, of course, in Colorado, but I think the analogy between this meat-test and a septic process in the lungs a very close one. The piazza life in Colorado can be made most attractive and comfortable, and a piazza can be arranged, as one in my house is, with a stove and blinds, furnished with rugs, bed, etc., and enclosed with glass on the north. In this way we offer an inducement to be out of doors, it is not taken as a task, and the nights also can be spent in pure air.

A life on a ranch in Colorado would seem to offer to the invalid an ideal method of being in the air and light, and I have at present some patients who are certainly improving rapidly on ranches. But they do not represent the average invalid, as they are selected cases, especially adapted for the life, with youth, strong digestion, and entire absence of fever, making the experiment worth the risk. I practised medicine at one time for several years among ranches in Colorado, Wyoming, and parts of Utah, and my experience has been that it is all a well man can do to digest the food that is eaten on most ranches, since it is with hardly an exception poor food, poorly cooked. Ranch houses, too, are built without regard to sanitation, while the temptations to overexertion, exposure, etc., are constant. Their isolation is to many a great drawback, meaning, as it does, the difficulty of obtaining medical advice if taken suddenly ill; and no amount of fresh air can compensate for such disadvantages. The life in a boarding house or in their own homes, with the constant use of the piazza, is probably the most practical arrangement for the greatest number of invalids and is the plan used by at least ninety per cent. of all invalids in Colorado Springs.

I consider that for a certain number of patients a life in a tent is really the nearest approach to the ideal life for a consumptive; I mean of course, with careful selection of the patient for such a life, and then a careful selection of tent, camping-site, etc., so essential to success. To most people a tent simply means what is ordinarily used in camping out, and it is this limited knowledge of tents that has brought them into disrepute with many physicians. The tent generally used is too low, made of thin duck, often without a floor, without proper artificial heat and is pitched in the open, becoming like an oven in the Colorado sunshine. Above all, such a tent has no proper system of ventilation and this is important, since a tent never ventilates itself by air coming through the canvas, as some people seem to think. The tent I have in mind is the result of considerable evolution in tent building, and although I have not yet been able to demonstrate its use with a large number of patients, I have myself lived in it both in summer and in winter, during rain and snow storms and for several weeks at a time. It is made of very heavy duck (12 oz.), is circular in shape, 18 feet high, 16 feet in diameter at the floor, with a wall 5 feet, 6 inches high. The top terminates in an iron ring 1 foot in diameter, to which the canvas is fastened, thus forming an outlet for heated air always open. The tent is supported by a center pole to which the ring is attached, and the tent can thus be elevated or lowered or its tension changed from within by pulleys. The floor is raised 8 inches from the ground, and is in 8 sections, thus being easily moved. The lower edge of wall is fastened several inches below the floor, 1 inch from it all around; this is to provide at all times an inflow of air that is gradual and without a draught, since this inch space in a circular tent represents an area of about 600 square inches, and the hole in the top for outflowing air some 123 square inches. In this way the tent cannot be close and is ventilated automatically and constantly. In other words, it is a circular tent, the bottom of the canvas forming a circle around the wooden floor but one inch from it all around and a little below the floor. This open space between floor and sides of the bottom of the tent allows air to flow into the tent at all times, while the hole at the apex or top of the tent allows air to flow out all the time. In this way the tent always ventilates itself day or night, with door shut or not, or when heated or not, or in any weather.

As the air has to turn a corner to enter the tent, it cannot come as a draught and as it enters through all the inch space surrounding the tent it enters slowly and without force, being evenly distributed but coming through collectively a large area, 600

1891. Also *Trans. Col. State Med. Soc.*, p. 321, 1894. Dr. Bull: "I have attended the Indians both here among the Sioux and in Idaho among the Bannocks. I have known many agency physicians and have talked with them. All agree that the older Indians say that they did not have consumption among them when they lived in tepees and in the open air. But as civilization advanced among them the Government has constructed log cabins and small frame houses for them, and they have given up the tepee for a short time in the hottest weather in summer. Now we have consumption the most prevalent disease. More than half of the deaths are from it."

square inches. The tent is easily heated by a wood or coal-stove, and yet in warm weather the constant interchange of air keeps it cool even without a fly. This tent should be fitted up in every way like a room. Cooking need not be done in it, but can easily be provided for at some house near by. Such a tent can be lived in for at least eight months in the year in Colorado at 6000 feet altitude, and in winter can be transported, if necessary, to some warmer climate south. The advantages of tent life are plenty of fresh air and diffused light, all of the twenty-four hours taken without effort. The psychological effects of such a life cannot be told here, but that it is a constant mental rest, that the novelty charms, and that a certain something, possibly the awakening of the hunting and migratory instinct inherited from countless generations of primitive ancestors does affect beneficially the nervous system of the phthisical is undoubted.

The points I have endeavored to emphasize are that light and air are to-day the most powerful agents we have for the cure of pulmonary consumption; that this fact is often overlooked, and that attention is paid to cures of much less value; that the most perfect qualities of light and air are only found on high, dry plateaux of over 4000 altitude, and that, under such climatic conditions, not only is the quality of light and air more perfect than elsewhere, but the available quantity taken is in excess, as it is practical for the patient to be out and obtain it; that if possible a pulmonary invalid should be out doors every hour of the twenty-four, as indoor air is not a cure for phthisis, and that a piazza life can be arranged for and made as comfortable as in a room. Ranching, as generally utilized, is a dangerous life for the average invalid, owing to bad food, exposure, over exertion, etc. A selected number of patients can be induced with benefit to live a tent life provided the tent is properly selected and managed on the plan I have suggested. Thus, while avoiding the ills of civilization from which our patient is escaping, we so control the new environment of nature as to avoid all its dangers, and obtain all its benefits.

CLINICAL MEMORANDUM.

ARREST OF DEVELOPMENT; SPINA BIFIDA, AND CLEFT PALATE.

BY W. A. McFARLANE, M.D.,
OF SPRINGVILLE, N. Y.

Spina Bifida.—In looking up the literature on this subject, I find that nearly every article deals with the surgical treatment of this affection without much reference to its etiology. The following cases have some points of interest:

Mrs. X., aged twenty-four years, married, primipara, on August 5, 1883, gave birth to a female child that presented a tumor in the lower dorsal region of the spine. The babe died in convulsions four days later. During the sixth week of gestation the mother had received a severe injury to the spine by having a chair pulled from under her as she was about to sit down. This injury afforded a very good explanation for the cause of the deformity of the child.

On October 18, 1886, she gave birth to a second daughter who was deformed in the same manner as the first. The child lived two weeks and died of exhaustion. The mother had complained of some pain in her back during her second pregnancy, due probably to the injury which she received while carrying her first child, for she had not met with an accident during her second pregnancy. I attended her in her second confinement, but not in the first. In the case of the second child the tumor was situated in the lower dorsal region, was about 2½ inches in length by two in width, and was elevated above the surrounding tissues about three-fourths of an inch, was transparent, and of a dark-reddish or purple color.

I applied a truss with a concave pad, simply for the purpose of protection. This comprised the treatment, the parents objecting to any operation. The father and mother were very much disappointed in the result of this pregnancy, and I was immediately called upon for an opinion as to the possibility or probability of their ever having a child that would be all right. My experience was insufficient, neither could I find anything in books nor journals that would warrant me in giving advice either way. In my dilemma I counseled with Dr. Skene of Brooklyn, my former teacher, stating all the facts in my possession, and his reply was "to try again, for she might do better next time." He also advised the use of the syrup of the iodid of iron when she became pregnant again, during the second, fourth, sixth, eighth, and ninth months. When she became pregnant again this treatment was adopted and carried out. On May 14, 1890, I had the satisfaction of delivering her of a female child, perfect in every way.

To add to the difficulties of deciding this important question there was a family history which was not good. A sister and her daughter had heart disease, and in the daughter's case was probably congenital. She afterward died of chronic Bright's disease at the age of sixteen years. A brother's child was born with an amputation of the left forearm near the elbow.

Dr. John Ashhurst, in Pepper's "Practice," mentions the fact that Salzman observed spina bifida in two children born of the same mother, and Camper noticed it in twins. Dr. L. Emmett Holt of New York reports a case in the *New York Medical Journal*, Vol. 46, in which the first and second child had spina bifida, the mother afterward giving birth to a healthy well-formed child. No statement is made, however, in regard to her treatment. In the *Medical and Surgical Reporter*, Vol. 58, Dr. Samuel Wolf of Philadelphia reports a case in which the mother gave birth to two children having the malforma-

tion. He outlined a plan of treatment which consisted in a careful regulation of the diet, the administration of hypophosphites, lactophosphate of lime, cod-liver oil, etc. He was unable, however, to test his plan of treatment on account of the patient's moving out of his district, but he learned later that she gave birth to one child, at least, that was not deformed. These are the only cases I have been able to find reported in which a mother has given birth to two children having this deformity.

Cleft Palate.—Mrs. Y., on September 2, 1894, gave birth to a male child having cleft palate. It was weak and died four weeks later. August 2, 1896, she was confined again. This child was perfectly formed, and is living at the present time and is in good health. During her second pregnancy she received treatment which consisted in the administration of the syrup of the iodid of iron, the same as in the case preceding, and the results were entirely satisfactory. She was confined again on April 20, 1898, at seven months. This child had talipes varus of the left foot, and in place of the fourth and fifth toes there was a gelatinous mass extending back to the middle of the metatarsal bones. She had taken the iron irregularly. The family history of the mother was not good; an uncle had died of locomotor ataxia, her mother had goiter and died of apoplexy at fifty years of age. The mother of the child had a sister who had hysteria.

THERAPEUTIC NOTES.

Treatment of Bright's Disease.—NESTOR TIRARD ("Albuminuria and Bright's Disease") inculcates the following principles of treatment of this disease: In the acute form of nephritis rest in bed, restricted diet, the wet pack, diaphoretics and cathartics are to be employed during the first few days, until an increase of the amount of urine voided and the absence of hematuria denote that the renal engorgement has subsided. Until this occurs, nitrogenous food and active diuretics are contraindicated. A strict milk diet is administered when possible, but in case digestive disturbance is produced thereby, small amounts of broth of chicken, veal or mutton may be added or substituted. Persistent vomiting should be combated by small doses of hydrocyanic acid, preparations of bismuth, drop doses of tincture of iodin, or small doses of creosote or carbolic acid.

In coma or convulsions active cathartics, as croton oil, are to be administered, and if persistent headache is present, small doses of calomel combined with compound pill of colocynth are given. The wet pack is preferred to the hot-air or vapor bath, as being more convenient of application and of equal efficiency. Restlessness and insomnia are to be combated with the bromids, hyoscin and, sometimes aconite. If anasarca exists to such a degree that relief is not afforded by purgatives and the wet pack, the skin over the malleoli may be punctured to allow the serum to drain off. Digitalis and caffein are indicated as diuretics after the hematuria has disappeared. During convalescence exposure to cold, and any muscular or mental strain must be avoided. Strict attention must be paid to the diet as long as albuminuria persists, and the non-astringent preparations of iron and arsenic should be given as tonics.

In chronic nephritis, if any cause can be found—as malaria, syphilis or suppuration—this must be treated, using mercury with great care, should it be indicated. In cases exhibiting excessive dropsy and muscular weakness, rest in bed is indicated; but when the patient's strength is good and there is but slight anasarca, a moderate amount of outdoor exercise is beneficial. The question of withholding albuminoids from the diet must be decided by the effect produced on the individual patient, though no nitrogenous food should be allowed if hematuria exists. The only limit to the amount of albuminoids to be allowed is the ability of the patient to digest them. Although sometimes a strict milk diet will cause the albuminuria to disappear, it is not, as a rule, wise to confine the diet too strictly to milk. If the patient's habits have been such that a bad effect is produced by a complete deprivation of alcohol, a small amount may be allowed, but it must be always largely diluted and taken only at meal times. If these conditions are observed, the form in which it is taken is of slight importance; and if no loss of appetite or indigestion results from the withdrawal of alcohol, none should be given. Diminution in the amount of urine voided may often be corrected by copious draughts of water, or, if the patient can bear it, of milk. The cardiac tonics—strophanthus, digitalis and caffein—are indicated, and the alkaline diuretics if there is no hematuria. Dropsy is to be treated by purgatives, such as the compound powder of jalap and the salines, given in doses to be regulated by the effect produced on the patient; by the carbonates and citrate of lithium and the citrates and tartrates of sodium and potassium; and, when the heart and lungs are in good condition, by small doses of pilocarpin given in connection with the wet pack. The same agents are to be employed in the treatment of uremic symptoms. Dyspnea should be treated according to its cause, engorgement of the lungs or weakness of the heart or uremic poisoning. The use of morphin is not recommended. Life in a warm, equable climate is to be desired and light and non-exciting occupation should be followed if possible.

Treatment of Ozena with Citric Acid.—HAMM (*Munch. Med. Woch.*, April 11, 1899) recommends the application of citric acid in ozena, as the best means of taking away the terrible odor, which not only disgusts all with whom the patient comes in contact, but also often destroys the appetite of the afflicted individual. Hence, the mere removal of the odor is often followed by a marked improvement in the patient's general condition. The citric acid, however, has also a slight beneficial effect upon the nasal lesions. It can be used either pure, or better mixed in equal parts with sugar of milk. The nose is thoroughly cleansed in the morning, and the powder is then blown into it, and the insufflation is repeated at noon and at night. The deodorizing effects continue some days after the discontinuance of the powder, and as the citric acid has no harmful action, it may be used as often as is necessary.

Liquid Thiolum to Relieve Pain.—NIKULIN (*Deut. Medizinal-Zeitung*, April 17, 1899) has used pure liquid thiolum to relieve the pain of contusions, abscesses, acute and chronic gout and rheumatism, neuritis and myositis, finding it beneficial in promoting absorption as well as in stilling pain. In the acute cases the results followed more quickly than in the chronic ones. The thiolum was painted upon the affected portion of the body with a brush, several coats being applied, and was allowed to dry. It was then covered with a bandage to keep it clean, and two days later another application was made if necessary. At the end of the treatment the excess of the substance was washed away with warm water or alcohol. In no case was any irritation of the skin observed, even after repeated applications of thiolum.

Treatment of Acute Gastritis in Children.—The first step in the treatment of this disease is to see that the stomach is thoroughly emptied of all irritating matter (PEPPER, "Keating's Cyclopedia," vol. v). If the child has not vomited very freely the stomach should be thoroughly washed out, either by lavage, or if that cannot be employed for any reason, by administering warm water and ipecac. After the stomach has been well emptied no food must be allowed until the organ has become entirely quiet. Vomiting may be controlled by administering cracked ice or albumen-water. Calomel in minute doses should be given if an offensive diarrhea is present. Bismuth is often of use, but sometimes the cautious use of morphin is necessary. But the stomach will usually become quiet after the withdrawal of all food sooner than as a result of medication. Fever should be treated by sponging the body or by the tepid bath. Antipyretics should be used only in very exceptional cases. The return to the ordinary diet must be very gradual.

Treatment of Pertussis.—CHENEY ("Keating's Cyclopedia," vol. v). The patients, of course, should be isolated and allowed to have plenty of fresh air both by day and night and should be allowed plenty of good nourishment. The drugs to be employed are: First, antiseptic agents, the best of which are the vapors of carbolic acid, cresolin and thymol, and quinin, which can be included in this class. It is very valuable, if the child can retain it, given in doses according to the age of the patient—$\frac{3}{20}$ of a grain for each month and 1½ grains for each year of the child's age—three times a day. Secondly, antispasmodics, of which the most useful is bromoform, which should not be given in solution but on sugar in a spoon, in doses of 1 drop every four hours, increasing the dose by one drop each day until an effect is produced. Antipyrin in combination with bromid of sodium is also of much value in the treatment, given in doses of ½ a grain of the former to 2 grains of the latter, for a child of eight months; 1 to 2½ grains for a child of fifteen months, and 2 to 3 grains for a child of from two years and a half to four years of age. Belladonna may be given in small doses, repeated until the physiological effect is produced.

Fatal Poisoning by Benzine.—SPURR (*Lancet*, June 3, 1899) records the death of an epileptic woman, aged twenty-six, fifty hours after taking about an ounce of benzine. Only a few cases of poisoning with this very common substance have been reported. In most of them the symptoms have been of a narcotic character. In this instance the patient complained of a severe burning pain in the mouth and throat, and although she was given a strong emetic of mustard and water soon after the accident, there was collapse rapidly progressing to a fatal termination. Swallowing soon became well-nigh impossible. At the post-mortem examination the mucous and submucous coats of the esophagus, stomach, and duodenum, were found to be intensely inflamed, and in the duodenum there were erosions of the mucous membrane, but no perforation. The brain, lower portions of both lungs, the liver, spleen, and kidneys were all intensely congested. The absence of narcotic symptoms was thought to be due to the prompt administration of the emetic.

Xeroform, Externally and Internally.—BARSKY (*Rev. de Therap. Medico-Chir.*, May 15, 1899), after using xeroform in 417 cases (in 34 of them internally), formulated the following conclusions in regard to its action: (1) Xeroform although not a powerful antiseptic is a most serviceable one. It is decomposed by the alkalin fluids of the body into bismuth and tribromophenol. The former makes an insoluble compound with ptomains and renders them innocuous, and acts mechanically to prevent the entrance of microbes. The latter constituent has a germicidal action. (2) It is not changed by light, air, or heat. It can be sterilized repeatedly up to 120° C. without alteration. (3) It is not only without odor, but it dispels the bad odors which come from ulcers of the skin, or suppurating cavities connected with the genitals or alimentary canal. (4) It possesses drying properties to a high degree. It does not form a crust over a wound, nor stick to the surface, but is carried with the discharges into the dressing. (5) It has an analgesic and a hemostatic action, and favors the growth of healthy granulations, and so hastens the healing. (6) It is not at all toxic, and does not exert any irritation either upon the wound or the surrounding tissues. It was used in the form of a powder, as a salve, in gauze, and in bougies. Internally it was given in an emulsion, the dose being from 3 to 8 grains, three times a day. It was prescribed for acute and chronic gastric troubles, and for urticaria.

For an Early Morning Diarrhea.—LEMOINE (*Nord Med.*, p. 86, 1899) thinks that the morning diarrhea, occurring especially in nervous individuals with an excess of hydrochloric acid, can be favorably affected by a suitable diet. Roast or broiled meat should be taken at supper time, and no vegetables. He gives his patients 2 to 4 grams (℥ss to ℥j) of bicarbonate of soda before the evening meal, and at bedtime 10 grams (℥ijss) of gelatinized phosphate of chalk, either in milk or in syrup.

Diarrhea after meals occurs also in hyperchlorhydric persons. They should be put upon a correct diet, and should lie down after eating. Each meal should be followed by 2 or 3 drops of acetate of opium in a little water.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

STREET DIRT AND TETANUS, WITH SOME REMARKS ON TREATMENT.

DURING the latter part of last week and the beginning of the present one a number of tetanus patients have been under treatment at various New York City hospitals. A number of deaths from the disease have been reported in the city itself, and from its suburbs. We have had quite an epidemic of what the newspapers call lockjaw. It is not unusual at this time of the year and the history of practically all of the cases is the same. There is a wound from a firearm or piece of fireworks on the Fourth of July. The lesion heals usually with little difficulty, to reopen some eight days to two weeks later, though sometimes it does not, when the symptoms of tetanus show themselves and the case either runs a rapidly fatal course or convalescence is very protracted, and in most instances some "mark" of the disease remains forever after impressed upon the sensitive nerve-centers.

The development of tetanus after certain kinds of wounds inflicted in city streets is not uncommon. It occurs especially after contused wounds accompanied by slight laceration of the skin, or upon what may be called simply lacerated wounds. The bacillus of tetanus is absolutely and unalterably anaerobic, that is it grows only in the absence of oxygen. It is not like so many other anaerobic bacilli, facultatively aerobic, or capable of at least some growth in the presence of oxygen. It is only when the bacillus somehow becomes buried in the tissues away from all contact with the air that it finds a favorable nidus for growth in the human organism. Lacerated wounds or contusions with slight abrasions of the skin furnish just such an opportunity for growth away from the air. It seems that the dust of city streets, especially in the summer time, usually contains tetanus bacilli, so that the primary element necessary for the production of the disease is practically always at hand.

Notwithstanding that we possess an antitoxic serum that is effective in preventing the development of the disease in animals, its employment has done very little good in human beings. Cures have been reported from its use, but a certain number of tetanus patients always recover and there is more than a suspicion that it is mostly in the cases more or less chronic from the beginning, and in which recovery often takes place even under old methods of treatment, that the serum seems to be effective. Certain it is that a number of individuals afflicted with the acute variety of the disease die despite the very generous employment of the serum.

Even in the case of animals the fact of the matter is that the animal cannot be saved by ordinary subcutaneous injections of tetanus antitoxin if distinct symptoms of tetanus are already present. The injection to be effective must be given before the symptoms begin to show themselves. Recently it has been shown that intracerebral injections of tetanus antitoxin are effective in curing the disease in animals even when symptoms are at their height. A certain number of cases of tetanus in human beings have also been treated in this way, and with good results as far as the tetanic convulsions are concerned, though we do not always know the ultimate outcome of the case. Dr. Gibb reports a case in the *British Medical Journal* for July 1, 1899, in which, after the cure of his tetanus, the patient died of cerebral abscess eight weeks after the injections had been given.

This method of intracerebral injections undoubtedly has its objections. It is a serious operation, and its sequelæ are often apt to be serious even with the most careful precaution. Its employment seems to be justified in very acute cases, however, as the disease in such cases is practically always fatal. The ideal method of treating tetanus, however, is the one we quoted from Professor Landouzy of the University of Paris in reviewing his book on "Serum Therapy" ("Notable Books," MEDICAL NEWS, March 18, 1899). He suggests the use of prophylactic injections of tetanus serum in cases of suspicious wounds. Tetanus antitoxin has of late years been made of such high antitoxic potency that it requires but the injection of a few drops of the serum to absolutely preclude the possibility of the development of tetanus. This procedure is certainly worth trying in the case of all contused and lacerated wounds that have been exposed to contamination by street dirt, and especially when they have been inflicted by firearms. It could do no harm even if there were no tetanus germs present. The serum, though of such high antitoxic potency, is absolutely innocuous. It would certainly save a great many lives and save the individuals, too, from a most horrible death in the midst of the conscious agony of tetanic convulsions. No one has yet, we believe, reported the use of this method in America. It seems distinctly worthy of such a trial.

SERUM-THERAPY IN DIPHTHERIA.

THERE are still some ultra-conservatives who think, or pretend to think (the latter is not an unusual state of mind, and may easily be assumed in perfect good faith in cases in which a public statement has once been made on a subject) that diphtheria serum has accomplished nothing in reducing the mortality from the dread disease. To these the statistics of the New York Board of Health and of the European cities where the remedy has been properly tested, as presented by Dr. Biggs in this issue, cannot be expected to bring conviction. A few others, who are so obstinate in their misoneism that a new therapeutic principle is an obvious impossibility, may be added to this list. To all others the specific curative properties of diphtheria serum is now a matter of absolute science.

Yet the opposition to diphtheria antitoxin has not been without its good results. The jealous watchfulness over mortality statistics by the unconvinced has had its beneficial effect in making those statistics accurately representative of facts, and has had its influence in producing constant improvement in the quality of the serum supplied. The notoriety at once given to complications seemingly induced by serum, or to sequelæ of its administration, has led to a thorough investigation of these unlooked-for effects, and has brought about their more and more effective amelioration. It is well for scientific medicine, especially for therapeutics, that the conservative element in the profession is so strong. It saves many a premature acceptance of what seems at first a useful remedy. What good grounds there were for a reluctant conservatism in the acceptance of diphtheria serum as a remedy, may be judged from the fact that its first much-vaunted successes were really not due to the antitoxin at all, but to expectant treatment, for the serums first employed were of such low antitoxic value (fifty antitoxin units, and even lower) that whoever should pretend now to base statistics on the use of corresponding amounts would be laughed to scorn.

It is evident, however, that the day for true conservatism in the matter has gone by. Hesitation now degenerates into old fogyism—misoneism is, we believe, the newer and more elegant term for this halting entanglement in ideas that have been outlived. The seal of professional approval has been put on the new remedy not by any one school or clique in medicine, and the hearty approval has not been dictated by national or other extraneous motives. It has been the result of careful observation in hundreds of thousands of cases all over the world. Statistics can still, in certain places, be so manipulated and discussed, that there remains in some minds just a shade of doubt, but this is only true because prejudice exists. The sentiment of the profession on the subject all over the world is clear, beyond the shadow of a doubt.

We quoted some time ago in this column the Chicago diphtheria statistics, and we are glad to be able to give this week the New York statistics, each a striking contribution to the literature of the success of antitoxin therapy. The boards of health of the two cities have deserved well of the profession and of modern scientific medicine, for their work in the

collection and collation of the statistics, and for the thoroughly scientific manner in which the subject has been worked up and convincing conclusions evolved.

THE PLAGUE IN THE MIDDLE AGES AND NOW.

THE fearful epidemics of the plague which swept Europe at different times, from the Sixth to the Seventeenth Century, filled the public mind with a horror from which it has never freed itself, and which modern science has done little to remove. In the Middle Ages the people feared an unknown something lurking in the air or in the touch of the sick or in their food. They had good reason to fear it for it seized upon them in times of epidemic and after a few hours' illness they were dead. They filled their streets with smoke, they bore burning pitch and sulphur through the sick-rooms, they rubbed the walls of their dwellings with chalk, they washed their food in fresh water, they withdrew from all intercourse with their neighbors, and fled at the sight of a stranger, and if they had to go into the streets on some unavoidable errand, they wrapped themselves in flowing wide-sleeved robes which they could cast aside when they came to their own doors. Others rubbed themselves with oil, because it was believed that in Egypt oil-bearers seldom took the disease. Others followed the advice of Boccacio and warded off the "black death" by laughter and song and jest. But merry-making in the face of death demands a lot of courage, and if that was lacking, it had to be gained by stimulants, so that the sound of revelry often mingled on the night air with the rattle of the hurrying dead-cart.

We pride ourselves on our scientific knowledge and our freedom from superstition. Men with bravery as true as that of the soldier charging up a hill against the fire of the enemy have tracked this black monster by caravan route and by ship back to its home in India and China, where they watched its comings and goings until in Hong Kong in 1894 they finally caught it and named it. It was once an unknown evil; now it is called "bacillus pestis." Familiarity with its manner of living and multiplying has begotten a certain amount of carelessness perhaps on the part of investigators, a carelessness which cost Vienna dear last fall when the death of a laboratory attendant who had charge of some animals which had been inoculated with the plague bacillus was quickly followed by the death of the physician and nurse who attended him, and all Europe knew that the plague had broken out in its very center. Vienna was in a panic, and the unreasoning fear and the hasty erection of barracks for the reception of possible victims to the disease, the burning of everything suspected of having come into contact with "bacillus pestis," the closing of all hospitals to students, and the appointment of royal commissions to consider ways and means of preventing the spread of the disease, all show that the superstitious fear of the Dark Ages is not dead, but only sleeping, and that a breath from Asia would arouse it to all of its former cruel activity.

Are we really in danger of such epidemics as have prevailed in past times? This momentous question is as yet without a satisfactory answer. Europe has had two great visitations of the plague, one in the middle of the Sixth Century, beginning in Egypt about the year 542, spreading through Constantinople where ten thousand people are said to have perished in one day, through Liguria, Gaul, and Spain, and ultimately all over Europe, having lasted a half century, during which time it caused the death of some millions of inhabitants. The second great epidemic was supposed to have originated in China in 1334, and after spreading through India and Persia, it reached Europe in 1347, and twenty-five million people fell before it during the next four years. Since that time there have been many epidemics especially in the Eighteenth Century, numbering their hundreds of thousands of victims but these epidemics have all been minor ones in comparison with the two great ones spoken of above.

If Europe has been free from this "black death" for nearly a century such has not been the good fortune of Africa and Asia. Little is known about the conditions of health in the centers of these two continents, but there is reason to believe that there are at least four regions where the "bacillus pestis" has its permanent abode, and from which it sallies forth from time to time to taste new blood. One of these is in Central Africa, one in Arabia, one in Mesopotamia, and one in Central Asia, from which the Chinese epidemics arise.

Whatever may be the means we possess to-day for the prevention of the spread of the disease, and as

they have not been fully tested it is not certain what their real value is, our means for curing those who fall sick with the disease are not much better than the Middle Ages possessed. It is estimated that in the Hong Kong epidemic of 1894 ninety-five per cent. of those who contracted the disease died. In other places the mortality has ranged from eighty to ninety per cent. There are no reliable records of the percentage of mortality of the epidemics of the Fourteenth Century, but it could not have been much worse.

It is encouraging that the recent outbreak in Vienna was so completely controlled. As far as it goes this speaks well for our knowledge of disinfection. Unfortunately it does not go very far toward proving our superiority to "bacillus pestis." The conditions were not ripe for its coming. It had been carried artificially under favorable conditions of warmth and moisture and nourishment in glass tubes from India to Vienna. It was an exotic there at that time, and no doubt was as tender as exotics usually are. At the times of epidemic the conditions for its growth everywhere out of doors have been favorable, else it could not have naturalized itself so rapidly. Hence it is unsafe to argue that because this sporadic development of plague did not spread further that a natural epidemic could be as easily stopped. There are men who have been fighting the plague in India for the last two years, who say that such would not be the case. They argue if the extraordinary powers given to the sanitary experts in India—powers which allow them to burn whole villages and to keep the inhabitants absolutely isolated—did not prevent the spread of the disease that Europe with its solidly built houses would be even more helpless before a real epidemic.

People often express surprise that any one can work in a laboratory with deadly germs of all descriptions and not contract some disease. To the initiated the habits and possibilities of attack of the different bacilli are as well known as are those of serpents or tigers to keepers of a menagerie. Occasionally by an accident some one falls under a lion's paw or an elephant's trunk, and in a similar manner some laboratory worker contracts diphtheria, or typhoid, or cholera. These happenings, however, are pure accidents, and neither the menageries nor the laboratories will ever close for the lack of men who are willing to disregard a danger which owes its power to their own carelessness.

ECHOES AND NEWS.

The Plague at Alexandria. — Three cases of bubonic plague were reported at Alexandria, Egypt, July 9th. The inhabitants are said to be discontented with the sanitary precautions and threaten trouble if the disease continues to spread.

Tetanus in 1898.—There were seventy-three deaths from tetanus in Greater New York last year. Of the number twenty-three occurred in the Borough of Manhattan, thirty-four in the Borough of Brooklyn, and one in the Borough of the Bronx.

Bubonic Plague on Shipboard.—It is reported by wire that the "City of Pekin" is quarantined at Nagasaki, and the American "Maru" at Yokohoma (both of the San Francisco-Oriental Line) with cases of bubonic plague aboard. Two deaths from this disease have occurred on the "Maru."

The Progress of Yellow Fever.—At Havana, Cuba, 2 cases of yellow fever were reported July 6th. At Santiago from June 15th to July 10th there were 148 cases and 28 deaths. Vera Cruz, Mexico, from June 29th to July 6th, 25 deaths. On the bark "Dolores Romano" at Vera Cruz July 1st 7 cases were discovered.

The American Electrotherapeutic Association. — This association will hold its ninth annual meeting at Washington, D.C., September 19, 20, and 21, 1899. Willard's Hotel has been chosen for the headquarters and special rates have been made for all interested in this meeting. Many able papers have been promised and a very successful scientific meeting is assured.

Scarlet Fever at West Point.—A slight epidemic of scarlet fever broke out among the cadets at West Point, July 11th. The prompt application of quarantine measures quickly brought it under control. During its sway the naval cadets from Annapolis on board the schoolship "Newport" arrived to pay a visit to the post. The quarantine rules prevented their landing, and they sailed away, without having grasped the hands of their brothers in the army. At last report no new cases had appeared, and the dress parades had been resumed.

The Buffalo Laboratory and the English Parliament.—In the English House of Commons, July 11th, in replying to a question of Sir Charles Cameron, the Parliamentary Secretary of the Foreign Office, said the attention of the Foreign Office had not been previously called to the fact that, owing to the deaths from cancer, the New York Legislature had endowed a laboratory at Buffalo to study the disease, but, the Under Secretary added, the British Chargé d'Affairs at Washington, would forthwith be asked to furnish the Government with all possible information regarding the institution. This recent interest

in the Buffalo laboratory has been aroused by the statement that investigations now being conducted there point strongly toward the confirmation of the germ theory of cancer. The somewhat startling statistics published last winter by Dr. Roswell Park setting forth the prevalence of cancer in New York State have been seriously questioned. Dr. Park informs us in a personal letter that in view of this fact, he is having his statistics carefully scrutinized in their minutest detail by experts preparatory to a subsequent statement.

Yellow Fever and Quarantine at Santiago. — General Wood in command of the Department of Santiago de Cuba is adopting heroic measures to stamp out yellow fever. An absolute quarantine against all officers and employees of the government, except those belonging to the department, has been established about the city. The mayor is directed to close all American hotels and saloons, to forbid liquor dealers to sell intoxicants to Americans, and to arrest all intoxicated Americans or loiterers in saloons. The principal hotels and saloons are designated by name. The pack-trains have been ordered to establish camps outside the city, and all the troops have been moved to Songo, except one company at Morro Castle. The headquarters of all the departments have been moved to Crispo, and the railroad and steamship lines are forbidden to bring Americans into the city. No ships are permitted to touch at the wharves. The strictest regulations have been established for the protection from fever of the soldiers at Morro Castle. Supplies are to be left at a road depot, and will be taken to the soldiers by teams from the camp. No travelers will be permitted to leave without having undergone five-days' detention in camp. On July 12th Captain Thomas M. Woodruff, adjutant of the Fifth Infantry, died near Santiago of yellow fever. Captain Woodruff was a native of the State of New York, but was appointed a cadet at West Point from the District of Columbia.

Letter from Major Harvard at Santiago.—Surgeon-General Sternberg has received a letter from Major Harvard, Chief-Surgeon at Santiago, which gives an interesting review of the yellow-fever situation there. The letter is dated July 5th, and says: "Fever broke upon us suddenly almost without warning, the first case in a dirty lodging-house in town, but the second and third cases almost simultaneously in the barracks. We have no doubt that the city is infected in various places, but especially in the barracks lately occupied by four companies and band of the Fifth Infantry, from which have come the great majority of our cases. The barracks and hospitals have been evacuated, as well as all other public buildings, and all our troops are in camps. The first two companies are now free from yellow fever, but the last two have continued to furnish many cases. On the 2d and 3d inst. these infected companies were disinfected, and sent into the foothills, five miles away, where we expect good results. Up to this evening we have about 104 cases, including 15 civilians, with total deaths of 23. Our general hospital is now under canvas, but I hope to be able to have a frame structure put up. All our cases with the exception of a Cuban, and a Spaniard, are Americans, and as all our troops are out of the city we necessarily expect a prompt decrease of the epidemic for want of material to feed upon. I have nothing but high praise for all the medical officers on duty in this city."

Assignments of Volunteer Medical Officers to Regiments at Various Posts. — Volunteer officers of the Medical Department have been assigned to regiments as follows: To the Twenty-sixth Infantry, United States Volunteers, headquarters Plattsburg Barracks, N. Y., Major Charles F. Mason, surgeon; Captain Frederick A. Washburn, Jr., assistant-surgeon; First Lieutenant John E. Boyd, assistant-surgeon. To the Twenty-seventh Infantry, United States Volunteers, headquarters Camp Meade, Penn., Major Ogden Rafferty, surgeon; Captain James H. Hepburn, assistant-surgeon; First Lieutenant Leonard K. Graves, assistant-surgeon. To the Twenty-eighth Infantry, United States Volunteers, headquarters Camp Meade, Penn., Thomas C. Chambers, surgeon; Captain S. Chase de Krafft, assistant-surgeon; First Lieutenant Allen J. Black, assistant-surgeon. To the Twenty-ninth Infantry, United States Volunteers, Fort McPherson, Ga., Major Charles L. G. Anderson, surgeon; Captain James C. Minor, assistant-surgeon; First Lieutenant Lomax S. Anderson, assistant-surgeon. To the Thirtieth Infantry, United States Volunteers, headquarters Fort Sheridan, Ill., Major John R. McDill, surgeon; Captain James J. Erwin, assistant-surgeon; First Lieutenant Albert H. Eber, assistant-surgeon. To the Thirty-first Infantry, United States Volunteers, headquarters Fort Thomas, Ky., Major Joseph N. Henry, surgeon; Captain Abram L. Haines, assistant-surgeon; First Lieutenant Ralph L. Porter, assistant-surgeon. To the Thirty-second Infantry, United States Volunteers, headquarters Fort Leavenworth, Kansas, Major Frank C. Armstrong, surgeon; Captain John W. Hereford, assistant-surgeon; First Lieutenant William H. Cook, assistant-surgeon. To the Thirty-third Infantry, United States Volunteers, headquarters Fort Sam Houston, Texas, Major B. Albert Lieberman, surgeon; Captain W. E. Parker, assistant-surgeon. To the Thirty-fourth Infantry, United States Volunteers, headquarters Fort Logan, Col., Major James E. Shellenberger, surgeon; Captain Frank W. Foxworthy, assistant-surgeon; First Lieutenant Patrick J. McKenna, assistant-surgeon. To the Thirty-fifth Infantry, United States Volunteers, Vancouver Barracks, Washington, Major Julius A. Schuelke, surgeon; Captain Luther B. Grandy, assistant-surgeon, First Lieutenant John A. Metzger, assistant-surgeon.

MEDICAL MATTERS IN NEW YORK.

REPORT OF CONTAGIOUS DISEASES FOR THE WEEK ENDING JULY 8TH — A CHRISTIAN SCIENTIST IN BELLEVUE HOSPITAL — A DEATH FROM RABIES — THE STRAUS MILK DEPOTS — IMMIGRANTS REJECTED ON ACCOUNT OF DISEASE — DEATH OF DR. F. W. FABRICIUS AT SANTIAGO — RECOVERY FROM TETANUS — "CHRISTIAN SCIENCE" OR "EDDYISM."

THE Board of Health makes the following report of

contagious diseases in New York City for the week ending July 8, 1899: Measles, 216 cases, and 13 deaths; diphtheria, 191 cases, and 42 deaths; laryngeal diphtheria (croup), 10 cases, and 6 deaths; scarlet fever, 125 cases, and 7 deaths; smallpox, 3 cases, and 1 death; chicken pox, 12 cases; tuberculosis, 98 cases, and 140 deaths; typhoid fever, 16 cases, and 10 deaths; cerebrospinal meningitis, 4 deaths.

In some inexplicable way a man who claimed to be a Christian Scientist, an "Eddyite" or "Divine Healer" and able to cure every disease afflicting the patients, got into Bellevue Hospital one day last week. He told the patients that the attendant physicians at the hospital were their worst enemies, and were merely experimenting on them for the benefit of the higher classes. The man had elaborately printed cards, on the back of which were crosses in red, and "P. J. Durvin, 285 Bowery," also the announcement that he and the Savior were able to cure every manner of disease. Durvin succeeded in passing through several of the wards before he was interrupted. It is said that he then left the hospital by the "most direct route." The patients were all more or less excited over the visit.

Charles N. O'Neil, four years of age, living at Montclair, N. J., was bitten in the face by a dog June 1st. The following day he was taken to the Pasteur Institute in this city, where he was treated by inoculation. The crisis had been passed and recovery seemed certain, when the boy developed marked symptoms of rabies and died July 16th.

The Nathan Straus milk depots have been opened at various points in the tenement-house districts and on the recreation-piers. Pasteurized milk and fresh milk cleansed by the centrifugal process is sold by the glass for one cent, and pure and modified Pasteurized milk are furnished in bottles for infants at nominal rates, or free to those too poor to pay.

The medical examiners at the port of New York, during the month of June, 1899, examined 30,754 immigrants. Of these 126 were rejected as suffering from loathsome or contagious diseases.

Acting Assistant-surgeon Frederick W. Fabricius of the United States Army, formerly a practising physician in this city, twenty-six years old, died the death of a hero at Santiago de Cuba on Sunday, June 25, 1899. When yellow fever first made its appearance among the American troops, Dr. Fabricius, although not an immune, plunged into the work of life saving with such energy that he soon exhausted his physical powers, and within a week fell a victim to the dreaded disease. He died five days after he had been attacked by the fever. Dr. Fabricius was graduated from the Bellevue Hospital Medical College, class of 1893, and was an interne at Bellevue from 1894 until 1896. He was afterward connected with the Metropolitan Hospital for the Insane. When war began between the United States and Spain the young physician offered his services to the government, and was appointed acting assistant-surgeon in the army. He was first stationed at Fortress Monroe, Va., and last December was transferred to Santiago de Cuba, where he held the position of pathologist and bacteriologist at the United States General Hospital up to the time of his illness. Dr. Fabricius was unmarried. He had a brother and an uncle living in this city.

Joseph Reinberg, twelve years of age, one of the victims of the Fourth of July fireworks, who had received serum treatment, both intracerebral and subcutaneous, was reported July 17th as convalescent. Some of the firecracker wadding which was taken from the wound in his hand has been sent to the laboratory of the College of Physicians and Surgeons for examination as to the presence of tetanus germs. There seems to be reasonable grounds for the belief that the pulp from which firecrackers are manufactured is made from the dirty scraps of paper collected from the streets, and therefore supplies the source of tetanus infection.

A much-advertised meeting of the Medical and Legal Relief Society was held at the Waldorf-Astoria on the evening of July 13th to take steps toward devising a bill for presentation in the New York Legislature to restrain the practice of Eddyism or Christian Science. The movement was evidently ill-advised and improperly organized. The members of the society and the representatives of the medical profession were conspicuous by their absence. The meeting was captured by a strong representation of Eddyites, and the effort resulted in a fiasco. As Mr. W. A. Purrington pointed out in a recent letter to the New York *Sun*, it seems obvious that attempts at legislation in the matter should not be made ill-advisedly or without due organization. In confirmation of this Mr. Purrington narrates the history of an effort made in 1898 by Senator Coggeshall to secure the passage of a bill that would have restricted the practice of Eddyism. At its hearing in committee so many Eddyites, most of them in skirts, were present that adjournment was had to the Senate Chamber. Apparently no one spoke for the bill and no one of note against it. After the usual platitudes concerning liberty and the customary depreciation of medicine as an unfinished science, the Senator is reported to have smiled, bowed to the ladies, and abandoned the bantling upon Mrs. Eddy's doorstep as cheerfully as he took it from its parent, whoever that may have been. It was another instance of an enthusiastic and organized few carrying their point, while the unorganized multitude was indifferent and apathetic.

Mr. Purrington's letter is so clear upon the relation of existing law to Christian Scientists that it seems quite worth while to quote freely from it. He says: "No medical law of any State enjoins or prohibits any system of medical practice. No law forbidding the practice of Christian Science or any other system of treating the sick, no matter how foolish, has been proposed. Those who assert the contrary do so ignorantly or with intent to mislead. What medical laws require, and in the opinion of the Supreme Court of the nation and of almost every State properly require, is that no person shall practice medicine before he has pursued a proper course of study and furnished some evidence that he has a fair knowledge of the human economy and the sciences relating thereto. This regulation applies to Roman Catholics, Protestants, and Jews. It is objected to by Christian Scientists and

Spiritualists, who stoutly maintain that to require the same education of them as of others engaging in the same business is to infringe their liberty of conscience and right to worship in their own way, although it is undeniable that when a man has once obtained a license to practice medicine upon proof of his scientific attainments he may follow any system he chooses. He may, if he sees fit, rely solely upon mental processes. Every physician does largely take into account and rely upon the effect of the mind upon the body, especially in certain classes of cases. There are few to-day who pretend that the high potencies of homeopathy have any medicinal action, and it was a realization that their effect was due to the patient's imagination that led Mrs. Eddy, as she says, into her own extraordinary system. But homeopathists admit the existence of disease. They often administer drugs as heroically as regular practitioners—sometimes more heroically. They use surgery skilfully. In fact, it is often difficult to differentiate them from regular physicians by their practice alone; nor was there ever a time when they did not claim to be called physicians. The Eddyites, on the other hand, although eager to dub themselves 'doctors of Christian Science,' declare that they are not practitioners of medicine. Mrs. Eddy, as was fully pointed out in the *North American Review* for March, condemns not only drugs, remedies, and instruments, but even hygiene, exercise, and bathing. Her method of curing disease is first to deny its existence and then to argue with it as one would argue with a Congressman. Herein lies at once the danger of her crazy method and the immunity of its practitioners from punishment under the law of this and many other States. A druggist who prescribes a proprietary nostrum or so simple a remedy as rhubarb or chalk mixture may be convicted of a misdemeanor. Our Supreme Court has so held in several cases. But it also has laid down in Smith *vs.* Lane (24 Hun., 632) the narrow rule that the use of drugs, medicines, or instruments is an essential element of medical practice, holding, in substance, that the medical law was intended only to protect those seeking treatment *secundum artem* from false pretenders to skill in the use of dangerous drugs or instruments, but not to protect from their mistake or folly, persons who, lured by wonderful promises of cure, submit themselves to the treatment of those avowedly discarding ordinary medical methods. This case, expressly approved of in Ohio, Rhode Island, and perhaps other States, is the joy and bulwark of Christian Scientists. It was held to be inapplicable under the Nebraska and Illinois statutes; but from the last Legislature of the latter State the Eddyites are said to have secured a proviso, in the new medical law adopting its rule.

"It will be remembered that a letter in the *Sun* of June 9th, the accuracy of which has not been denied to my knowledge, showed that when Mr. Carol Norton, Mrs. Eddy's apostle hereabouts, was asked if he would dare to exclude medical aid and treat severed arteries, fractures, strangulations, and contagious diseases by mental processes he twice wrote that he preferred to shelve the questions. It must seem startling to a layman that a druggist violates the medical law by prescribing rhubarb, while a Christian Scientist who 'thinks at' the severed artery of a child is exempt from the operations of that statute.

"But does it follow that we are without remedy under existing law? It would seem not. If it can be demonstrated that a Christian Scientist has caused death by excluding proper medical or surgical treatment and substituting his mental processes—in such cases, for instance, as those submitted to Mr. Norton and 'shelved' by him—it ought not to be difficult to obtain a conviction of manslaughter, if not of murder. The societies for prevention of cruelty to children can act in the premises. English courts are extraordinarily lenient with fanatics, but although Wagstaffe escaped punishment prior to the enactment of the Prevention of Cruelty to Children statute, that law seems to have been passed in consequence of his acquittal; and recently another member of the 'Peculiar People,' whose child died under a similar treatment by anointing with oil in Apostolic fashion, was convicted of manslaughter. If memory serves, Mr. Gerry, some years ago, took from a missionary a child whose fractured arm the father was treating solely by such anointing; and the bishop forbade the parent to go back to his post. There is no reason why Christian Scientists should not be compelled to report births, deaths, and contagious diseases under the usual penalties for disobedience. If they say that it is wrong to compel them, who do not believe in disease, to report its existence, once more the answer is simple: Mrs. Eddy herself has reported in print that her first husband, Colonel Glover, died of 'yellow fever,' that insidious disease. But after all, that which will destroy Christian Science is the true exposition in the reviews and daily press of its absurdities, its vulgarities, its false pretences, as well as its dangers. It does not seem possible that a sane or reverent mind or one with any sense of humor could accept seriously the preachment of the exceedingly shrewd, but very ignorant and ungrammatical old lady, once of Lynn but now of Concord. And it is safe to say that unless Christian Scientists can win some temporary advantage by cheap martyrdom the time will come very soon when sane and reputable persons, many of whom now accept the doctrine ignorantly, will blush with shame to think they ever could have been disciples of Mary Moss Baker Glover Patterson Eddy, whose name seems to be legion."

MEDICAL MATTERS IN PHILADELPHIA.

A LAW TO PREVENT POLLUTION OF THE SCHUYLKILL RIVER—LICENSES FROM OTHER STATES DO NOT QUALIFY THE HOLDER TO PRACTISE MEDICINE IN PENNSYLVANIA — MORE "FAITH CURE" NOTES—TETANUS RESULTING FROM FIREWORKS' INJURIES —THE BOARD OF WATER EXPERTS—DIPHTHERIA IN SOLDIERS' UNIFORMS — DR. CATTELL ELECTED PATHOLOGIST TO THE PHILADELPHIA HOSPITAL—APPOINTMENTS OF MEDICAL MEN BY GOVERNOR STONE—PERSONAL.

AT the thirty-third annual meeting of the Pennsylvania State Board of Health, held this week, a regulation was adopted for the prevention of pollution of the Schuylkill

River. The new regulation, which is based upon power recently vested in the State health authorities by an act of legislature, absolutely prohibits the pollution of this stream by deposits of excrement of all kinds, from any source whatsoever. Recent official investigations having shown the presence of widespread contamination of the Schuylkill by the sewage of dwellings, institutions, and manufactories situated along its banks, the importance of the new order can scarcely be exaggerated. The board, now that it possesses the power to do so, will at once begin the work of abating the nuisances, by rigorous enforcement of the new law; and, it is to be hoped, without fear or favor of either individuals or of corporations.

Congratulations should be extended to the Pennsylvania State Medical Council for its recent successful efforts in the courts to uphold the standard of legal requirements for the practice of medicine in this State. In a suit which was decided this week by Judge Simonton, a mandamus was refused compelling the Medical Council to issue to a Dr. George A. Ludwig, a license to practise medicine, without the necessary qualification of examination. The physician in question is a graduate of a Baltimore medical school and a licentiate of the Maryland Medical Examining Board, and he applied for a license in this State on such credentials. The license was properly refused, so he carried the question to the courts, evidently to test the legality of the Medical Practice act of this Commonwealth. Judge Simonton, in refusing to grant the mandamus, based his decision upon the fact that the medical law of Maryland, under which the petitioner was qualified, fails to meet the demands of the medical law of Pennsylvania. This decision should form a valuable precedent, to deter, in future, licensed physicians from other States where the qualifications may happen to be trivial, from attempting to evade the Pennsylvania law, by presenting such credentials in lieu of standing the regular examination required in this State.

It becomes painfully monotonous to have to record, week after week, the far-reaching evils of the "faith-cure" and allied insanities in this vicinity, but once again your correspondent feels called upon to note still another death from the practise of the delusion. This time it is the case of a young child, now dead of scarlet fever, whose father not only refused to call in medical attendance for the little one, but even failed to report the illness to the health authorities of the town. The father, Jacob W. Gracely, by name, is reputed to trust rather to the Lord than to physicians for the treatment of disease, and he is himself following out this line of belief in his own case, for he is also ill. The authorities of Allenton, where this individual lives, have placed him under arrest, not for believing in the Lord, but for violating the law requiring the notification of contagious diseases, but sentence has been suspended pending the prisoner's indisposition.

More "faith-cure" news comes from a small borough in Chester County, to the effect that a petition, signed by most of the residents of the place, has been presented to the local school-director, requesting the reconsideration of the appointment of a school-teacher who is alleged to hold firmly implanted Christian Science views. It is stated that the teacher complained of has openly advocated the teachings of this sect, made "converts" to the faith, and aired her views of the question in the schoolroom. The school directors are divided about the removal, and the deadlock may have to be broken by the courts.

Contrasted with New York City, where such an epidemic of tetanus has followed the Fourth of July, Philadelphia may consider herself exceedingly fortunate. This city has not escaped, however, as the five fatal cases of tetanus from injuries by fireworks testify. In addition to these, there are several other cases, convalescents, or of mild infection. Judging from the large number of accidents suffered by Fourth of July celebrators in Philadelphia, the number of tetanus cases has been few.

The three water-experts appointed by the mayor, Messrs. Rudolph Hering, Samuel H. Gray and Joseph M. Wilson, have just visited Albany, N. Y., where they inspected the model 15,000,000-gallon water-filter, considered one of the best-constructed plants in the world. As yet, the experts have not advanced any definite plan of water-purification for this city, and their decision in the matter will not be arrived at until after extensive inspections of water works in various parts of the country and until after careful consideration of every phase of the question. The public prints are full of all sorts of rumors attributed to the board of experts, but their endorsement of any method of water-supply suitable for this city will remain problematic until the publication of their official report to the mayor.

Owing to the vigilance of the factory inspectors and the health authorities, a quantity of soldiers' uniforms ready for delivery to the Schuylkill Arsenal this week, were found to have been exposed to infection by diphtheria; the articles of clothing were immediately confiscated and sent to the disinfecting-station for sterilization. This is the second instance of diphtheria-infected clothing which has been reported in this city within a fortnight, and the detection of the danger testifies to the watchfulness of the factory inspectors, who made the discovery in both instances.

At the last meeting of the Board of Charities and Correction, held this week, Dr. Henry W. Cattell was elected pathologist to the Philadelphia Hospital to succeed Dr. John Guiteras, who recently resigned.

Governor Stone has announced the following appointments of medical men during the past week: Dr. J. L. Forwood of Chester, to be a member of the Quarantine Board for the port of Philadelphia, vice Dr. Ernest La Place, whose term expired July 1st, and Drs. John H. Gibbon of Philadelphia and Herbert A. Arnold of Montgomery County, to be assistant surgeons of the National Guard of Pennsylvania, with the rank of first lieutenant, with assignments to the Sixth Regiment, Infantry. Governor Stone has also commissioned as medical officers of the National Guard Major Francis R. Packard, surgeon, and Captain R. W. Montelius, assistant-surgeon, both with rank from June 14, 1899; and Lieutenant Walter Boardman, assistant-surgeon, with rank from July 11, 1899.

Among the medical profession of this city nearly "every one who is any one" seems to have joined in the midsummer rush Europeward. Among the latest departures and those who expect to sail during the next few days may be mentioned Drs. James C. Wilson, J. Montgomery Baldy, G. Hudson Makuen, Solomon Solis-Cohen, Howard F. Hansell, and M. S. French. Dr. Henry C. Chapman, who has been abroad since early last spring, is expected to return the latter part of August.

The number of deaths in Philadelphia during the week ending July 15th reached a total of 482—an increase of 47 over those of last week, and a decrease of 11 from those of the corresponding period last year. Returns of contagious diseases are as follows: Enteric fever, 40 new cases, with 9 deaths; diphtheria, 64 cases, with 17 deaths; scarlet fever, 35 cases, with 2 deaths; and cerebrospinal meningitis, a single case, and 2 deaths.

SCIENTIFIC MEDICAL JOTTINGS FROM AMERICAN TROPICAL COUNTRIES.

CARRION'S DISEASE.

A DISTINCT contribution to South-American medicine is the recent publication of a volume on "La Maladie du Carrion" by a friend of the martyr scientist, whose heroic inoculation of himself, unfortunately with fatal result, has added so much to our knowledge of the disease.

The disease has been known as long as history goes back in Peru. When the Spaniards under Pizarro landed in the country they were stricken with it. It has been known by many names, nearly all of them having reference to its occurrence in Peru, or at least in the Andes Mountains. It has been called verruga des Andes and verruga Andicola, the wart of the dweller in the Andes; verruga de Castille, because of its occurrence among Spaniards when first brought to European notice. The new name proposed for it, La Maladie du Carrion, seems to be a worthy tribute to the fearless young investigator who made the true character of the disease known, though his inoculation of himself cost him his life.

During the building of the railroad from Lima to Oroya a number of the workmen were prostrated by a fever that often proved fatal. It was practically always complicated by a cutaneous eruption resembling that of verruga Peruana, and it was a matter of great doubt as to whether two diseases coexisted. It was thought that the fever might be a serious form of malaria during which, owing to lack of resistive vitality, the verruga Peruana succeeded in getting a foothold. Carrion, a medical student, inoculated himself with material taken from one of the cutaneous lesions and is considered to have demonstrated that the fever and the eruption were symptoms of one and the same disease. He developed a cutaneous eruption and a very high fever which proved fatal on the thirty-ninth day. He had the satisfaction of knowing before his death that he had solved the problem of the identity of the two diseases.

As the disease may last for months in certain chronic forms it would seem that physicians on our seaboard should know something of it as they are liable to meet with examples. The eruption occurs in two forms, a miliary and a tubercular or, as they say in Spanish, mular form. The miliary form is not unlike prurigo at times or sudamina, though the little indurated nodules which are very superficial may become umbilicated and so resemble variola. It may be localized when it occurs on parts especially subject to irritation, as the face, hands, and feet, and the knees and elbows. Often it is universal. The tubercular form occurs as nodules at first to be felt rather than to be seen in or under the skin and later reaching good size, sometimes as large as a small orange. These large nodules sometimes retrogress but oftener form adhesions to the skin and break down. Fever always occurs, sometimes just after the eruption. The height of the fever seems to depend on the amount of the eruption. Plentiful external eruption relieves the system of toxins by elimination as it were. The nodules have been found on the serous membranes and in all the internal organs, even in the bladder and testicle, and in Peyer's patches. The fever is often of quotidian type, with afternoon elevations; sometimes, however, it is of tertian type, and it may at times be very irregular, but it never fails to make its appearance some time in the course of the disease.

SANARELLI'S BACILLUS NOT THE CAUSE OF YELLOW FEVER.

Dr. A. Matienzo in the *Gaceta Medica*, the periodical of the National Academy of Medicine of Mexico, Vol. XXXVI., No. 10, in a note on the bacteriology of yellow fever gives the details of six cases of the disease in which he sought carefully, and with the technic advised by its discoverer for Sanarelli's bacillus but failed to find it in any one of the cases.

In conclusion, he says: The bacillus claimed by Sanarelli as the cause of yellow fever, and whose presence cannot be demonstrated after repeated investigations such as I detail here is evidently not the true cause of the disease. Sanarelli himself admits that it cannot be found in nearly one-half the cases, and this flagrant violation of Koch's law of pathogeneity should be enough to condemn the idea of its specific etiology for yellow fever. Novy, working under Roux at Paris, has shown recently that Sanarelli's bacillus by its acid reaction with tournesol and its production of gas in glucose solution resembles the colon bacillus, though it has certain similarities with the bacillus of Eberth that seems to show that it belongs rather to the family of the typhoidal bacillus.

The most important fact that speaks against its specific pathogeneity for yellow fever is that its vitality is not inhibited in the least by exposure to a temperature of fifteen degrees below zero, and that this exposure does not even temporarily paralyze its germinative powers.

Dr. Matienzo agrees finally with Novy that the germ of yellow fever, very probably like that of hydrophobia and other well-known diseases, is so small that it is beyond the power of the best lenses we have at present; that it is "in the realm of the infinitely little."

MICROBES AND THE SCENTS AND COLORS OF FLOWERS.

According to *La Nature*, Dr. Domingos Freire, the well-known yellow-fever expert of Rio Janeiro, and whose inoculations with yellow-fever serum have attracted so much attention, claims to have found that most of the flowers harbor micro-organisms of various kinds. Some of these microbes are startlingly similar to some of the pathogenic varieties of bacteria. Dr. Freire expresses the opinion that the presence of these bacteria is not merely a passing incident in the life of the flowers but that they are intimately associated biologically with them as hosts. He thinks that a sort of symbiosis exists and that the color and scent of the flowers are really due to bacterial parasites that flourish on them. He has found without doubt that in certain cases at least, a microbe can be cultivated from the surface of a flower, which in culture media reproduces the color of the flower or one very similar to it. He has found, for instance, a pinkish leptothrix that grows on the Rosa Rothschild which is always of a pink color. In the same way he has demonstrsted that the odors of flowers may be reproduced in cultures of microbes obtained from them.

Dr. Freire considers that some at least of the bacteria that he finds so commonly on flowers may be pathogenic for man. Certain forms he has not been able to differentiate from well-known pyogenic microbes. The bacillus pyocyaneus seems to occur in connection with certain tints. Very often he has found on flowers certain micrococcic forms resembling the ordinary pus-cocci, which he considers have been deposited there from the air and either have been able to reproduce themselves or at least have retained their vitality. As they are by no means infrequent and as the flowers possess ample opportunities for the collection of floating micro-organisms from the air and as especially such as are grown during the winter months in warm living rooms, are continually in the midst of conditions of heat and moisture that would favor the multiplication of microbes. Dr. Freire advises against close contact with such flowers especially by delicate persons. It is this property of microbe cultivation it would seem, rather than any supposed noxious organic product that is thrown off from them that constitutes the real danger of having flowers in living rooms.

BACTERIA AND TOBACCO.

An almost as surprising development of bacteriology is that touched on by Nuttal in the June number of the *Contemporary Review*, but in this case it is as helpful agents that they are found at work. Certain observations in Cuba and Florida seem to make it clear that during the time that tobacco is maturing after being cut down there is a development in it of bacteria. It is this that raises the temperature of the tobacco and if it is allowed to proceed too far will spoil the leaf. The growth of these bacteria produces the characteristic qualities of the special form of tobacco, and in the tobacco of different countries it is not so much the varieties in the tobacco plants themselves or the conditions of moisture, soil, and climate under which they have grown as the varieties of colonies of bacteria that develop on it which makes the ultimate differences in the mature product.

COMPARATIVE MILDNESS OF PURULENT OPHTHALMIA NEONATORUM IN WARM CLIMATES.

Dr. J. S. Fernandes in the June number of the *Gaceta Medica* of the National Academy of Medicine of Mexico reasserts, as the result of observations and comparisons made during the last ten years, that the disease type of purulent ophthalmia (gonococcal) of the new-born is much milder in warm climates than it is in Europe. This was asserted some time ago at the Paris Society of Ophthalmologists, but was received with some incredulity. Dr. Augustin Chacon found it to be the fact in Mexico and now Dr. Fernandes confirms it for Havana. In many cases the gonococcus was found, yet, in some of these patients under the ordinary treatment for catarrhal conjunctivitis, they were on a fair way to recovery. The complications and serious sequelæ were much rarer than in Europe. We do not know that it has ever been noted in temperate climates that purulent ophthalmia neonatorum is less virulent in the summer time, yet this ought to be the case if it is the temperature alone of warm climates that causes the difference in the types of the disease. Dr. Fernandes suspects that there are other factors at work though he is not able to designate them very definitely.

CACODYLIC MEDICATION—PENETRATING WOUNDS OF THE CHEST—ANOTHER CANCER PARASITE—MOVEMENT OF THE RIBS IN PLEURISY—CASTRATION FOR TUBERCULOSIS OF THE TESTICLE—SUTURE OF TWO FRACTURED CLAVICLES—TUBERCULOSIS OF THE SPLEEN—SYPHILITIC GLOSSITIS IN A WOMAN.

AT the Academy of Medicine, June 6th, GAUTIER said that he had used cacodylate of soda in profound anemia, in malarial cachexia, and in many cases of confirmed tuberculosis. Although cacodylic acid contains 54·3 per cent. of metallic arsenic, it is certain that the cacodylate of soda is not an ordinary arsenical compound. It causes the fever of phthisis to fall slowly but steadily, at the same time that it promotes assimilation and increases the patient's weight. The stomach will support indefinitely a daily dose of from 1½ to 3 grains and almost the same amounts may be administered subcutaneously to an individual who cannot take without disturbance $\frac{3}{100}$ of a grain in Fowler's solution. This difference in poisonous action between organic and mineral arsenic is explained by the experiments of Besredka who found that mineral arsenic injected into the peritoneum or under the skin is absorbed by the leucocytes and passed on in an organic form to the other cells of the body, especially those of the nervous system. If mineral arsenic is injected so that it comes into immediate contact with the nervous centers, before it can be changed by the leucocytes, it is found that the fatal dose is only the one-hundredth part of the amount which is fatal if the drug is first changed by the leucocytes.

The cacodylates are irritating in large doses, stimulat-

ing in therapeutic doses. They excite reproduction of the lymphoid corpuscles, especially the polynuclear ones, which protect us from infectious bacteria and their products, and cause the rapid multiplication of the red corpuscles. Cacodylic medication, therefore, appears to be an excellent remedy to regulate oxidization and consequently to renew the blood and tissues. In phthisis the cacodylate of soda should be given hypodermically in doses of from 1/3 to 3/4 of a grain daily. This medication should be continued daily for a week and then omitted for a week, to be resumed if the appetite begins to fail or the temperature to rise.

ROBIN thought that cacodylic medication should not be classed with arsenical as the action of the former excites, and that of the latter restrains organic changes.

GAUTIER said that the restraining action of arsenic follows large doses. In minute doses its action is also an excitant one.

At the session of June 13th DELORME, in speaking of the treatment of penetrating wounds of the chest, laid stress upon the good effects of absolute quiet, antiseptic dressing of the wound and, according to circumstances, the administration of morphin, ether, caffein, etc. On account of the excitement usually attendant upon a shot from a pistol, morphin is particularly beneficial to quiet the nervous condition. The patient should not be moved for some days.

Artificial serum for loss of blood is a valuable restorative, but it should be injected slowly lest it cause pulmonary congestion and increased respiration, and so bring about fresh hemorrhage. If hemothorax threatens life, the chest should be opened and the hemorrhage stopped by ligatures or tampons. On account of the danger of infection from the bronchi, pneumothorax after a penetrating wound of the chest demands immediate surgical interference.

LUCAS--CHAMPIONNIERE entirely disagreed with Delorme's treatment of hemothorax. In such conditions the additional traumatism of an operation may readily cause death, while apparently hopeless cases if left to themselves, may recover.

At the Academy of Sciences, May 23d, CHEVALIER said that he had isolated a fungus from cancers which could be cultivated in bouillon made from a cow's udder and in other media. The microscopic appearances of the molds varied greatly according to their age and the medium employed. Inoculations of the cultures into the skin of guinea-pigs, rabbits, and dogs produced not only local tumors, but secondary visceral nodules and a general cachexia. Microscopically the tumors resembled sometimes sarcoma, sometimes fibrosarcoma, sometimes carcinoma. In spite of these facts Chevalier hesitated to announce as yet that this fungus was the cause of the original tumors in man from which it was isolated.

June 12th, BOUCHARD and GUILLEMINOT reported that by means of the X-rays they had ascertained that in recent unilateral pleurisy, the ribs of the affected side move less, and are held more obliquely than on the well side. In chronic pleurisy and in long-standing unilateral phthisis, this obliquity still more increased. In persons so affected the range of motion of the ribs is much decreased so that respiration becomes largely abdominal even in women.

At the Surgical Society, May 31st, DELBET spoke of the advantages and disadvantages of castration in tuberculosis of the testicles. In seventeen out of twenty cases which he had examined, the disease was limited to the epididymis. It followed that indiscriminate castration was not to be advised. On the other hand, the three cases showed that it is sometimes necessary. He admitted the favorable influence of castration upon tuberculosis of the seminal vesicles and prostate, but a similar good effect may follow an epididymectomy for tuberculosis. None of these reasons, therefore, warrant the removal of a sound testis, which will continue functionally active, if its vessels remain, even though its excretory duct be removed. Removal of both epididymes does not necessarily produce impotence. The best incision is an anterior one opening into the tunica vaginalis. The testicle can then be examined and the diseased portions removed.

POIRIER said that a patient whom he had reported to the society as a case of cure of tuberculosis of the seminal vesicles still had the disease, as a recent examination showed. In five cases he had removed nodules from the epididymis only to find other nodules a few weeks later. Hence it is desirable to make a high incision and to inspect the whole epididymis and vas deferens. Many times it will be found desirable to remove these structures in their entirety.

At the session of June 7th, GUINARD discussed two cases of fracture of both clavicles by direct violence. Pluyette, the surgeon in charge of one patient, a young man of twenty-two years of age, made an immediate resection and suture of the left clavicle, and a month later the right one was treated in the same manner, as it had thrown out an enormous callous. The result on both sides was satisfactory. Guinard considered that the condition of the other patient precluded any operative effort. Two months after the accident, the man left the hospital with union of both bones, but with an enormous callous. He held that suture should not be performed immediately but should be reserved or postponed until it is plain that there is a defective callous or a false joint.

At the Medical Society of the Hospitals, June 2d, WIDAL described a peculiar type of tubercular enlargement of the spleen, characterized by an especial group of symptoms, and to which attention has not yet been called. The patient in question began to suffer from pain in the left hypochondrium at his thirty-first year. Later a tumor slowly developed, which grew till it reached the inguinal region, and occupied the whole left half of the abdomen. It was hard and lobulated. The patient died in eight years, never having had ascites. There were two cardinal symptoms, however, a cyanosis, manifest especially in the extremities and face, and an increase in the red blood-cells to about 6,200,000 and of the white ones to 6,000. There was no modification in the numerical relation of the different kinds of white corpuscles. At autopsy the spleen was found to measure twelve inches in length and to weigh over seven pounds. There

was scarcely any splenic tissue remaining, the whole organ being composed of tubercular nodules and sclerotic tissue. Microscopical tubercles were found in the liver, pancreas, and kidneys.

MOUTARD-MARTIN saw a case of primary tuberculosis of the spleen, in which there was an increase in the blood-globules, but no cyanosis.

ACHARD also mentioned a case of primary splenic tuberculosis.

At the Society for Dermatology and Syphilography, June 8th, NELATON said that the sole radical treatment of lupus is to remove it, making an incision beyond the diseased tissue as if for cancer. He had employed in a number of instances scraping and cauterization, but he had obtained a complete cure in only one instance, a case in which the lupus was upon the buttock.

BALZER showed a female patient with a glossitis in the third stage of syphilis. This trouble is very rare in the female, only 2 out of 850 syphilitic women being so affected according to Barthelemy.

FOURNIER said that this difference in sex is inexplicable. The tongue is best treated by injections of calomel. Sometimes the injections will cause the lesions to disappear. The use of corrosive sublimate is not to be recommended, as it may injure the teeth.

SOCIETY PROCEEDINGS.

THE AMERICAN PEDIATRIC SOCIETY.

Abstract of the Proceedings of the Eleventh Annual Meeting, Held at Deer Park, Maryland, June 27, 28, and 29, 1899.

DR. WILLIAM P. NORTHRUP of New York, President of the Society, called the meeting to order at 10 A.M. He took for the subject of his address "The Teaching of Pediatrics." He said, in part: The American Pediatric Society is made up largely of teachers of pediatrics, and the discussion of the methods of teaching this subject are worthy of consideration at this time. We may ask, What place should the subject of pediatrics have in the curriculum? What number of lectures and what amount of time should be given to this subject in an undergraduate course? In answering these questions I must draw upon my own experience. In the whole scheme of instruction we may admit the primary importance of general medicine, general surgery, and obstetrics, and then pediatrics shares with gynecology the second place. Our course in instruction at present includes didactic lectures, clinics, and section-teaching. There is a wave of sentiment against didactic teaching and no doubt the reaction against the former complete dissertations on disease is justified, but the didactic lecturer has yet a function, which is to present to the beginner the salient points of a subject, to give the essentials of a subject. Certain diseases must, in addition, be seen clinically in order to understand them, and in addition to the regular clinic, attended by all, there should be section-teaching so that the student may get very near the patient, and if possible each student should be allowed to repeat the demonstrations. In this way gavage, lavage, lumbar puncture, etc., can be best taught.

He then described what he considered the best arrangement of hospital rooms and wards for teaching purposes, and gave a list of diseases that should be taught entirely by the chair of pediatrics. He was enthusiastic about the value of a steriopticon for teaching purposes. In regard to the status of a teacher of pediatics he said that in their school the professor of pedriatics is not a member of the governing faculty but both he and his chief of clinic receive a salary.

In the discussion which followed DR. ROTCH of Boston said: In the early history of Harvard University very little time was given to the teaching of pediatrics, but the importance of the subject has gradually become more fully recognized until it now holds the same position as any of the other branches of clinical medicine or surgery. There is continuous teaching from October to June, and five exercises a week are given. The teaching is divided into didactic lectures, clinical instruction, and what we call clinical conferences. The ward-material is used in connection with that of the out-patient department. The examination in pediatrics is compulsory. We also use the lantern and slides and find this a most valuable means of instruction. At the beginning of the course the time is devoted to teaching the students what is especially distinctive of the early years of life, and having been well grounded, first in what a healthy child should be, they are then taught about the diseases. At the clinical conferences one of the students reads a paper on some case which he has been asked to work up, and the paper is discussed first by the students and then by members of the staff. The professor of pediatrics holds a chair in the faculty on an equality with any other member of the faculty and receives a salary.

DR. J. P. C. GRIFFITH of Philadelphia: We are not as progressive in Philadelphia as they are at Harvard, but we are gradually recognizing the importance of pediatrics. At present pediatrics is an elective study at the University of Pennsylvania, but I am glad to say that I think most students recognize the importance of this branch of medicine. In teaching I follow very much the plan described by our president in his paper.

DR. HENRY D. CHAPIN of New York: My work has been mostly with post graduate students, and I find that a large number of them are not well grounded in the principles of pediatrics. I think this is largely due to the fact that college authorities have not appreciated the importance of pediatrics and have not given it the proper place in the curriculum. It should not be tacked on to obstetrics or to gynecology, nor should it be treated as a specialty. It should be taught as a branch of general medicine.

DR. BLACKADER of Montreal: It has been my custom to devote my didactic lectures mainly to a consideration of infantile development and the different ways in which a disease manifests itself in the child as compared with the adult. The teacher in McGill University is associated with the chair of medicine, is not a member of the faculty and has no emoluments.

DR. S. S. ADAMS of Washington: I think the matter of proper recognition does not rest so much with the colleges as with the men themselves. If they insist upon proper recognition they will receive it.

DR. COTTON of Chicago: At Rush Medical College we have just adopted a plan by which the junior students are to be thoroughly drilled in the preliminaries and the seniors are to be given actual clinical experience.

"The Increase of Weight in Infants Fed Artificially" was the title of a paper by DR. HENRY KOPLIK of New York. He said: During the past nine years I have conducted in connection with my dispensary clinic a laboratory for the artificial feeding of infants and for the purposes of the present study infants below the age of nine months were observed, and as many collected as would remain under observation for a protracted period. I have studied, first, infants fed from birth, or nearly so, with a modified cow's milk; second, infants fed with breast and cow's milk. The modified milk supplied to these infants was in all cases the same, being composed of cow's milk diluted with an equal part of distilled water and with six per cent. of sugar of milk added. Infants below three months received three ounces of this mixture; above this age an ounce was added for every month until eight ounces was reached, when full milk was administered. The infants were then systematically weighed. In some of the older children, who did not prosper on this Heubner-Hofman mixture, I increased the amount of fat. My patients were all taken from an ambulatory service in the slums.

Tables are appended to show the gain in weight in these twenty-five cases, and I may say that I believe it is quite safe to predict that an infant, if it has the breast only once or twice in the course of twenty-four hours, will thrive on the bottle much better than on the bottle alone, and I am convinced that it is not advisable to deprive the infant of the mother's breast, no matter how scant the secretion of the breast may be. It is very difficult to decide how much cow's milk should be given such infants because it is impracticable to measure the amount of milk secreted by the breast in question. An observant mother and physician will soon find out, however, how much additional milk should be given in any case.

DR. ROTCH: While this work is very interesting I think it is not at all scientific. We cannot make a test of any method of feeding by the use of ambulatory subjects for the doctor can never tell what such children are getting when they are away from his observation.

DR. KOPLIK: I admit the force of this objection. I have not attempted to show the value of any particular mixture, but merely to determine how much weight a bottle-fed infant should be gaining if it were prospering.

DR. ROTCH: That is exactly what you have not shown and what cannot be shown by this method.

DR. MORSE: It seems to me Dr. Koplik has simply reported the gain in weight of a certain small number of infants fed on a certain mixture, and did not report the number or condition of those that did not thrive under the same circumstances, consequently the work is without scientific value.

DR. WENTWORTH: If Dr. Koplik meant to recommend any breast milk as better than artificial feeding alone I shall have to take issue with him, because I believe it is a well-known fact that careful chemical analysis has shown that when the mother's milk is scanty it is also apt to be a poor milk.

DR. CHAPIN: It seems to me, however, that clinical experience shows that it is better to give the mother's milk even though the albuminoids be high and the fats low than to cut it off entirely for substitute feeding.

DR. BLACKADER: I am rather inclined to agree with the last speaker for it is no light measure to at once put a child on artificial food.

DR. WENTWORTH: I recognize the value of mixed feeding, and I only criticised Dr. Koplik's point that even a very scanty supply of milk added to the artificial feeding is better than artificial feeding alone.

The next paper, on "Porencephalus. Case and Specimen," was presented by DR. GEORGE N. ACKER of Washington. The patient was a male colored child, four years old, in whom the mother noticed, soon after birth, that the eyes had a peculiar appearance and that he did not move his right arm or leg. He never made an attempt to walk, or talk, and was quiet at all times except when hungry, when he would emit a peculiar shrill cry. The muscles were soft and flabby, with a noticeable atrophy on the right side and the right forearm was strongly flexed and could not be extended. During his stay at the hospital there were pronounced nervous symptoms and the temperature at one time reached 107° F. At the post-mortem examination, twenty-six hours after death, it was found that the right hemisphere weighed 19½ ounces and the left 14½ ounces. The defect in development of the brain corresponded pretty closely to the parts supplied by the middle cerebral artery and seemed to be due to some change in this artery. The fissuration was quite atypical.

"A Preliminary Communication on the Separation of Bacteria from Milk by Natural Processes" was read by DR. R. G. FREEMAN of New York. He said: I have previously expressed the opinion that raw milk, even when the conditions of the dairy are satisfactory, cannot be considered safe for administration without heating because it is likely to contain a considerable number of bacteria, and we cannot make sure that among these there may not be the organisms that produce diarrhea, typhoid fever, diphtheria, or other diseases. For that reason I desire to make a preliminary report on some work which, while incomplete, seems to show that the great bulk of bacteria which contaminate milk may separate from it by natural processes without the use of filtration, heat or preservative agents. If milk is allowed to stand until the cream separates, and then if a separate analysis is made of the milk and of the cream it will be found that the cream contains 300 times as many bacteria as the milk, and with the rising of the cream about ninety-nine per cent. of the bacteria are removed from the milk. This separation may be due to the better oxygenation of the upper layers, which induces the organisms to rise to the surface, or it may be due to their being

carried up by the fat globules in their process of inverse precipitation. Should this prove to be correct we may be able to pasteurize or sterilize the separated cream and then add it again to the practically germ-free milk for administration as a food.

The next paper, entitled "Sarcoma of the Cerebellum in a Child, Aged Four Years," was read by DR. S. S. ADAMS of Washington, D. C. The patient was first taken ill in June, 1897, the prominent symptoms being high fever and vomiting. Under treatment she apparently recovered in about a week, but a month later she began to complain again of intense pain in her head and right arm. This was followed by weakness of the legs, the child frequently staggering and at times falling. She slept well at night and seemed to suffer principally in the mornings and afternoons. A second attack of fever and vomiting developed and she lost control of her bowels and bladder. At the autopsy the diagnosis of cerebellar tumor was verified. The brain weighed thirty-nine ounces.

"Enlarged Bronchial Nodes" was the title of the next paper, read by DR. J. PARK WEST of Bellaire, Ohio. He said: Within a comparatively short time I have seen eight children in whom I have made the diagnosis of enlarged bronchial nodes and in every case the patient had come on account of the accompanying cough. In every case there seemed to be a more or less general involvement of the lymphatic system. Every child had enlarged cervical nodes. In six there were, in addition, large axillary nodes, and in five large inguinal nodes. All had large tonsils, two had adenoids that interfered with nasal respiration, and in three the spleen could be felt. It seems to me that the enlargement of these nodes was the local manifestation of a status lymphaticus.

"Report of a Case of Transposition of the Viscera of the Great Vessels, with Photograph" was read by DR. J. P. CROZER GRIFFITH of Philadelphia. The patient, a boy eight months old, began three months previous to admission to the hospital to have attacks of cyanosis and dyspnea, lasting about twenty minutes and occurring as often as half a dozen times a day. On admission the child seemed ill and was distinctly cyanotic. A systolic murmur was heard with greatest intensity at the pulmonary cartilage and at the third left interspace close to the sternum, as well as at the aortic cartilage and the apex. It was not transmitted to the axilla and there was no thrill. The diagnosis of pulmonary stenosis, probably associated with a perforate septum ventriculorum was made. The child soon sickened with what appeared to be symptoms of pneumonia, cyanosis increased, and he was so weak that he was treated purely symptomatically and the actual condition of the viscera was not investigated. I have here the post-mortem specimens which show the following peculiarities. The aorta arises from the right ventricle and passing upward arches slightly from left to right, then almost directly backward, over the right bronchus, and descends upon the right half of the vertebral column. The coronary arteries arise from the right ventricle. The pulmonary artery rises from the left ventricle to the left of and slightly posterior to the origin of the aorta. The liver lay chiefly to the left side and the spleen in the mid axillary line in the right hypochondrium. There are two supernumerary spleens.

DR. R. G. FREEMAN of New York then read a paper, entitled "Observations on Certain Abnormal Conditions in Livers of Infants and Children." He said: I have carefully studied the autopsy reports of some 500 cases at the New York Foundling Hospital, with reference especially to the conditions of the liver. In this investigation I have found that cirrhosis of the liver is very rare in infancy, as is also the condition of waxy liver. With regard to the condition of fatty liver I have found some points that quite contradict the ordinary statements given in the text-books, and am led to formulate the following conclusions: (1) Fatty livers occur very frequently in the infants and children that come to autopsy at the Foundling Hospital—about forty-one per cent. of all cases. (2) The condition of nutrition of the child apparently has no connection with the fatty condition of the liver, the condition of nourishment in the subjects having fatty livers averaging about the same as in the whole number of cases. (3) Fatty livers occur rarely in the chronic wasting diseases, such as marasmus, malnutrition, or rachitis and syphilis, unless such condition be complicated by an acute disease. (4) With tuberculosis fatty livers do not occur more frequently than in other conditions. (5) Fatty livers occur most often with acute meningitis, gastro-intestinal disorder, measles, and diphtheria.

"A Case of Meningitis Due to the Typhoid Bacillus" was reported by DR. A. H. WENTWORTH of Boston. The patient, four years of age, first seen October 1, 1898, had always been a delicate child but had never had any previous illness. For six days prior to entrance into the hospital she had been feverish, drowsy, without appetite, and was said to have been delirious at times. On admission there was considerable apathy from which she could be aroused without difficulty although she became quite irritable. The urine contained a faint trace of albumin. Its specific gravity was 1015. The examination of the blood showed 12,000 leucocytes per cubic millimeter. A provisional diagnosis of typhoid fever was made. The next day the nurse reported that twice during the night the child's body became rigid, the hands clenched and the eyes were rolled upward, this condition lasting about one minute each time. An examination of the eyes was made, but without result, and from fluid secured by spinal puncture no growth was obtained. The following day there was bulging of the right tympanic membrane and when paracentesis was performed there was an escape of air, but no fluid. Widal's test was negative, though the clinical symptoms were those of a moderately severe typhoid fever. On October 15th a second blood count showed 9600 leucocytes. On the 16th the child became very stupid and by evening was unconscious. Tonic and clonic convulsions and Cheyne-Stokes respiration supervened. On the following day strabismus appeared, and there was general rigidity of the muscles of the trunk and extremities, with spasms at intervals. Death occurred on the seventeenth day.

Lumbar puncture was performed a few hours before death, and the spinal fluid obtained was turbid and soon showed a deposit of puriform material in the bottom of the test-tube. A careful study of this deposit by all methods showed a pure culture of the typhoid bacillus.

In considering the diagnosis I would say that in favor of typhoid fever there is the onset, the duration of the disease, the character of the temperature-charts, the enlarged spleen, the failure to obtain evidence of the presence of other diseases by means of physical examination, and the negative result of the first lumbar puncture showing the absence of meningitis at that time. As against the typhoid diagnosis there was the failure of the Widal test and the occurrence of doubtful convulsions in the early period of the disease. In favor of meningitis due to the typhoid bacillus there was the presence in the meninges of a purulent exudate which contained numerous typhoid bacilli, and the failure to detect the presence of other organisms by means of most careful bacteriologic examinations.

"Vaccinoid" was the title of the next paper, read by DR. F. FORCHHEIMER of Cincinnati. He said: The subject of this paper is the peculiar manifestations of vaccinia, which have usually been denominated false or spurious vaccinia. Recently the French investigators have done much work to show the relation of these conditions to vaccinia. According to their classification by vaccinoid is meant an atypical course of the lesions produced by the act of vaccination, and in their external manifestations they have the same relation to vaccinia that varicloid has to variola. The speaker reported a number of cases observed in his own practice with a careful study of the subject and offered the following conclusions: (1) Vaccinoid is always modified vaccinia. (2) Vaccinoid protects against variola. (3) This protection is less than that of vaccination. (4) Vaccinoid in the majority of instances is due to faulty method, rarely to increased resistance or immunity. (5) In primary vaccinations vaccinoid should always be followed by repeated attempts until either true vaccinia is produced, or until positive evidences of immunity exist. (6) In the presence of an epidemic of variola vaccinoid should be followed by revaccination, both in primary vaccinations as well as in revaccination. The more thoroughly vaccination is performed the fewer will be the cases of vaccinoid, provided the virus is perfect. Vaccinoid is an abortive vaccinia, and abortive vaccinia is not perfect vaccination.

"Acute Articular Rheumatism in Infants under One Year of Age, with Report of a Case," was read by DR. D. J. MILTON MILLER of Philadelphia. He said that from an extensive review of the literature upon this subject it seems that acute articular rheumatism in infants is very rare. A number of cases have been reported as such which would not bear the test of the essential features of the disease as seen in adults. The patient that he had observed is an infant nine months old with an attack of genuine acute polyarticular rheumatism. In the diagnosis of such a rare condition every other possible cause for the joint affection must be excluded before we can assert that a given case is rheumatic. The points necessary to be established in making such a diagnosis are: mobility, proneness to migrate from joint to joint, absence of all tendency to suppuration, frequency of inflammation of the cardiac serous membranes, the favorable influence of the salicylates, and a family history, together with the absence of such affections as are apt to be attended by inflammation of the joints. According to this test only nineteen undoubted instances of acute articular rheumatism occurring in infants under one year were found in the literature.

The next paper, entitled "Urticaria of Mucous Membranes," was read by DR. F. A. PACKARD of Philadelphia. He said: This paper is written to suggest the possible frequency of the condition of internal urticaria as an explanation of certain cases otherwise difficult to understand, such as the so-called "stomach cough" and "sore throat of indigestion." I have seen two cases of urticaria associated with asthma or bronchitis, and with the cases reported in the literature these make thirty-four in which the connection between the skin-lesion and the respiratory symptoms was quite close. The order of the occurrence is not uniform, and while in many cases there seems to be a balance between the cutaneous and respiratory lesions the two systems are frequently involved at the same time

"The Renal Complications of the Acute Enteric Diseases of Infancy" was the title of a paper read by DR. JOHN L. MORSE of Boston. The essayist said in part: During the Summer of 1898 I examined the urine of seventy infants ill with uncomplicated diarrheal diseases. They were all out-patients at the Infants' Hospital and hence many could not be examined more than once. All were under two years of age, forty-seven being under one year. The urine was obtained by catheterization, scrupulous care being taken as to cleanliness of the catheter. Tables showing the extent of the investigation and the results of the examinations are appended. I believe it probable that more- or less-marked degenerative changes occur in the kidneys in many, if not most, patients. These degenerative changes are due to the action of bacteria or toxins, usually the latter. Inflammatory changes are rare. Albuminuria occurs in about fifteen per cent. of all cases and casts are found in sixty per cent. of these. The presence of albumin and casts does not justify the term "nephritis," and is not of bad prognostic import.

DR. FLOYD M. CRANDALL of New York then read a report of "A Case of Scurvy in an Infant Six Weeks Old." The patient was born October 12, 1898. The father was not in good health, having long suffered from chronic rheumatism, while the mother, who had a valvular cardiac disease, following rheumatism, was anemic and did not recover from the effects of confinement for many weeks. The child was not strong and when seen in the sixth week there was a well-marked condition of scurvy. The child had never taken anything but breast-milk, which was very abundant, though thin and watery. So abundant was the supply that though the child nursed frequently it never emptied the breast and consequently only received "fore-milk," which contains a much smaller amount of fat than does the later milk. The child

was allowed to continue nursing, but pasteurized cream was given to make up the proper amount of fat, and the results were prompt and satisfactory so far as the scurvy was concerned, but the child subsequently died from an attack of pneumonia.

Dr. Griffith: In a recent text-book I find the statement, in italics, that in scurvy occurring before the stage of eruption of the teeth there is no characteristic lesion on the gums. In the collective investigation made by this society last year twenty-four such cases were reported. Of course the society did not assume the responsibility for all of these, but I feel that certainly all the reporters could not have been wrong.

"Congenital Cystic Kidneys, with Report of a Case" was read by Dr. E. E. Graham of Philadelphia. He said: I was called to see this baby about twenty minutes after its birth. It was well developed but distinctly cyanotic, breathing feebly, and the cyanosis appeared to be more marked than the heart's action and feeble breathing should produce. The body was limp and the child could not be aroused. Death occurred forty-five minutes after birth. The autopsy made four hours later showed a normal heart, small areas of lung tissue containing air; liver, spleen, and mesenteric glands normal, and both kidneys cystic.

"A Case of Multiple Osteomyelitis in an Infant" was reported by Dr. T. M. Rotch of Boston. The patient was a female infant, one month old, with a history of a previous erysipelas starting from the umbilicus and running down on the left leg. At the time seen the diagnosis of cellulitis and probable osteomyelitis was made. An incision was made along the inner side of the tibia and an abscess found under the periosteum. A second abscess appeared at the posterior border of the deltoid. Cultures taken from both these abscesses showed the staphylococcus aureus. The infant died nine days later and autopsy showed a multiple osteomyelitis.

The following officers were elected for the ensuing year: President, Dr. Henry Koplik of New York; secretary Dr. Samuel S. Adams of Washington; treasurer, Dr. J. Park West of Bellaire, Ohio.

THE INDIANA STATE MEDICAL SOCIETY.

Abstract of the Proceedings of the Annual Meeting, Held at Indianapolis, Ind., June 6 and 7, 1899.

The annual meeting of the Indiana State Medical Society held at Indianapolis has been a great success. The attendance and *esprit de corps* partook of the general activity of the community and inclination to hustle observable everywhere. Excellent papers were read and vigorously discussed, one or two of which deserve especial circulation, as, for instance: "Diphtheria and Antitoxin," by Dr. A. E. Powell of Marion, who reported an outbreak of the disease in the orphanage of his county. In substance he related that on January 15, 1899, a case of throat trouble developed in a female inmate, which was diagnosed as tonsillitis. There were sixty-eight children of all ages and both sexes in the institution at that time. Within the two weeks following twenty-five cases of sore throat occurred and in several of them microscopical examination revealed the specific bacillus of diphtheria. The early cases progressed favorably and it was not thought necessary to use antitoxin. Gradually, however, the severity of attacks increasing, its use was begun in the case of a girl, aged six years, who developed severe pharyngonasal diphtheria. As she improved in the beginning under the treatment the local manifestations disappeared, but later she succumbed to paralysis of the heart.

The second patient received 1000 units as an initial dose. This amount was repeated in twenty-four hours and the child recovered, although his heart was very weak. Three other children developed the disease in quick succession and were treated with like results, when it was determined to give an immunizing dose of the antitoxin to all of those remaining unaffected. Accordingly, to each of thirty-eight children, 500 units was administered. There were no skin eruptions in any case and no abscesses formed. None of those injected for immunization developed the disease.

This experience led the speaker to the following conclusions:

1. When in doubt about a case of sore throat it is safest to call it diphtheria and treat it as such in every respect.

2. Antitoxin is the most reliable remedy we have today in the treatment of diphtheria.

3. Antitoxin proves itself most valuable when administered early in the course of the disease and in sufficient quantity.

4. Antitoxin is a positive preventive of diphtheria when administered to those who have been exposed to the disease.

In striking contrast to this paper was that by Dr. T. J. Griffiths of Crawfordsville, who selected the subject of "Hydrotherapy in the Treatment of Diphtheria." He took occasion to rap the antitoxin treatment, along with most others that have preceded it, characterizing them as being in many instances blind, cruel, and irrational. After calling attention to the rapidity of proliferation in childhood and the conditions necessary for the rapid development of germs either in or out of the body, *viz.*, heat, moisture, and fertile soil, he proceeded by noting the fact that ice applied to the throat lowers the temperature of the part below that at which germs can thrive and grow. Ice, he said, is as certainly a specific for diphtheria as is quinin for malarial poison; no glandular engorgement or serous effusion ever takes place in the presence of the cold produced by the application of ice. Under this treatment no septic swabbing with any preparation of iron becomes necessary; no septic poisoning ever can or will take place in its presence; it is grateful, soothing, invigorating to the patient, and hastens convalescence without exhaustion. The same treatment is applicable in scarlet fever and in croup; no remedy is equal to it in certainty and rapidity of action. He has seen a child with that never-to-be-forgotten whistling respiration, cyanotic from deficient aeration relieved in a few minutes by the application of a snow-poultice. Cold

is non-toxic, is a tonic, germicide, and febrifuge, and is easily procurable and regulatable by the physician. He cited Pepper and May as authorities on the question of therapeutics of cold.

"The Clinical Features of Malaria as Seen at Camp Mount," by DR. W. T. S. DODDS of Indianapolis, held the close attention of the assembly on account of the peculiarities manifested in the persons of the recently returned troops from Cuba and Puerto Rico. The speaker said that in these subjects malaria does not present itself in its characteristic forms; the surroundings and environment have much to do in modifying the character which malarial manifestations assume. If the person infected be robust and healthy previously the greater the liability to a typical course of malarial fever. On the other hand, if he be anemic, and especially if he has had previous attacks, the course of the disease may deviate widely from the ordinary and typical form; he may or may not have febrile disturbance; if fever be present it is likely to be of low degree and assume the typhoid form. Lawrence places the febrile activity centers in the brain and assumes that as the malarial process progresses these centers become less and less sensitive to the presence of the parasite.

The temperature ranges about 99° F. and the subject presents a picture of tuberculous infection, often grows worse and finally presents symptoms both grave and obscure. Slight splenic engorgement, in addition to the emaciation, is about all a physical examination will reveal. The emaciation and irritability are progressive. Marked stomach and intestinal complications may intervene and the subject succumb to a fatal dysentery. While those who live in malarial districts may finally become immune so long as they remain in the same locality, if they change about they acquire as great a liability to disturbance as originally existed. The apathetic condition of the patient, the coated tongue, the pain in the head, back, and loins, and the enlarged spleen, in connection with epistaxis, closely resembles typhoid fever. In the congestive form the physical appearance does not correspond to the intensity of the trouble; the pulse is slow, the rhythm disturbed, and valvular murmurs are often audible; the patient is listless, pale, and exhausted; the extremities are cold and irresponsive to local heat or other applications and the case is alarming.

That typhoid fever may be complicated by malaria, and *vice versa*, is an accepted fact; the two diseases may be associated together and their symptoms, each distinctive, be plainly indicated by the clinical features of each. Other complications, such as pneumonia, enteritis, and acute rheumatism, may occur.

The treatment may appropriately be divided into 3 classes: (1) Complete rest; (2) specific medication; (3) treatment of complications. In the chronic form a pill containing strychnin, iron, and arsenic forms a good adjuvant to hydrochlorate of quinin, which should be followed by tonics, careful diet, and exercise in the open air.

"The Hematozoon of Malaria" formed a fitting subject to follow the foregoing paper, and its microscopical appearances were fully described by DR. THEODORE POTTER of Indianapolis.

DR. F. B. THOMPSON of La Fayette presented a paper on "Leucemia." He said that the disease is characterized by the persistent and rapid increase of the proportionate number of white blood-corpuscles, together with enlargement of the spleen and the lymphatic glands. It is uncommon among children; men are more liable to it than women, in the proportion of two to one. While heredity does seem to exert a great influence upon its occurrence, still there seems to be a condition of temperament or cachexia which is an important factor, especially so in some families. In all well-marked cases the skin presents the pale, waxy appearance of decided anemia; occasionally the tendency to exuberant deposit of pigment is well marked, giving the bronzed appearance of Addison's disease. With emaciation well marked the extremities may be edematous, or general anasarca or ascites may be present. Not known to be due to specific toxic elements the symptoms are those of an indolent septicemia. Insidious in its beginning the opportunity to examine the blood is not generally presented until the disease is well established. The chief element found to exist on examination of the blood is in the superabundance of myelocytes derived from the bone-marrow. Assuming the possibility of suppuration of the blood it is not difficult to understand why the leucocytes of the blood are so enormously increased. The post-mortem appearances of the spleen, lymphatic glands, liver, and kidneys are explained when regarded as concerned in the filtration of fluids and elimination of effete and toxic substances.

In its treatment arsenic stands almost alone, doubtless on account of its ability to check putrefaction and tissue metamorphosis. Quinin in large doses has been employed, but when long continued, 3 grains, four times a day will accomplish all that can be reasonably expected of it as a remedy. Oil of eucalyptus, which has been so highly recommended, the speaker has found of little service. It would appear to be essentially a septic disease and dependent upon a toxic agent for its causation. Primarily a disease of the blood, the glandular involvement occurs as a natural consequence.

DR. L. J. WILLIEN then read a paper on "Thyosanamin as a Resolvent for Scar-structure, Rendering It Pliable No Matter Where Situated." Derived as an extract from the oil of mustard by the addition of three or four times it weight of ammonia it forms colorless rhombic crystals having a garlic odor and very bitter taste. It produces both diuresis and diaphoresis in doses of from 4 to 8 grains, three or four times a week. It should not be administered oftener than once daily. It has been injected in doses as high as 2 drams into carcinomatous tumors without any stomach distress and without appreciable good effect upon the malignant growth. It has been recommended in cases of keloid, lupus, enlarged and tubercular lymphatic glands of the neck, sarcoma, fibroids, and syphilis. Its effects in cases of syphilis were manifested in the following case: J. G., aged fifty-six years, of good family history, given to the free use of

alcoholic stimulants, contracted some years ago a specific disease. Height 6 feet, weight 200 pounds, in 1896. He complained of vertigo, double vision, dizziness, and tendency to fall forward when walking. Numbness of the tongue and aphasia coexisted. The left side of the body became weak and was followed by cephalagia. Placed under a strong course of iodids and mercurials without any satisfactory results he repaired to the Hot Springs, returning in six weeks without any beneficial results. He consulted two prominent physicians in St. Louis and then went to Chicago for the same purpose. All agreed that he had a cerebral tumor. Confusion of ideas and impaired memory, diplopia, divergent strabismus, dilated pupils, vascular sclerotics, aphasia, numbness of the tongue, dysphagia, loss of strength and mobility of the left arm and leg, and persistent pain in the occipital region extending to the eyes and preventing sleep were marked at this time. He was given 15 minims of a 15-per-cent. solution of thyosanamin in equal parts of water and alcohol, hypodermically, three times a week. Four months having elapsed he is to-day regarded as a well man and able to attend to his business. Other cases of the same character, treated in the same manner, showing equal improvement, were reported. The good effects of the drug have been manifested even in cases of tuberculosis.

REVIEWS.

LEGAL DECISIONS, MEDICAL. By W. A. PURRINGTON, of the New York Bar. Counsel of the New York State Dental Society; Lecturer on Medical and Dental Jurisprudence in the New York College of Dentistry, etc. New York: E. B. Treat and Co., 1899.

THIS is a booklet of 105 pages, most of which is devoted to the citation of decisions in 131 cases at law, involving suits by, or against, physicians and dentists. These citations are from advance sheets of the *International Medical Annual*. The decisions are interesting to peruse but their compilation is of more value to lawyers than to physicians. The work contains a brief introductory article on the justification of State Examining Boards and medical laws and the means of enforcing these laws. To these are added "A Brief for the Prosecution of Unlicensed Practitioners," and a reprint from the Mew York *Medical Record*, of the author's article on "Manslaughter, Christian Science, and the Law."

CHEMISTRY: GENERAL, MEDICAL, AND PHARMACEUTICAL. Including the Chemistry of the United States Pharmacopœia. A manual of the Science of Chemistry, and its applications in Medicine and Surgery. By JOHN ATTFIELD, F.R.S. Sixteenth edition. Philadelphia and New York: Lea Brothers & Co., 1899.

AGAIN we find a new edition of this most comprehensive manual, the fifth edition to appear within the short space of ten years. It is hardly necessary to mention that all the newest discoveries and theories are embodied in this edition, and that the book presents the science of chemistry in a most lucid manner to the medical student and practitioner. Toxicology, general chemistry, analysis of physiological as well as of other materials are discussed, and the book presents a most complete treatise on this vast subject. It is a work fit as well for the student as for those in search of a good reference book.

It is most gratifying to notice that the metric system has been given the attention it merits. A complete index occupying sixty-three pages and embracing over ten thousand references greatly enhances the value of the book. Eighty-eight illustrations serve to explain the carefully compiled text. The author is thoroughly *au courant* in all the details of interest and embodies in his text all of the latest developments of chemical principles and the latest applications of chemistry to medicine and pharmacy.

THERAPEUTIC HINTS.

For Irritating Cough of Phthisis.—When not accompanied by much expectoration the following mixture is recommended:

℞	Codeinæ	gr. iv
	Ac. hydrochlor. dil.	ʒ ss
	Spts. chloroformi	ʒ iss
	Syr. limonis	ʒ i
	Aq. dest. q.s.ad.	ʒ iv.

M. Ft. emulsio. Sig. One teaspoonful at short intervals when cough is troublesome.—*Murrell.*

For Catarrhal Affections Following Measles and Whooping-Cough.—HOCK advises the employment of creosote, prescribing as follows:

℞	Creosoti	*m.* xv
	Saccharini	gr. ¾
	Ol. morrhuæ	ʒ iii.

M. Ft. emulsio. Sig. From 2 teaspoonfuls to 3 tablespoonfuls a day.

An Analgesic Lotion.—

℞	Atropinæ sulphat.	gr. ii
	Morphinæ sulphat.	gr. x
	Ac. oleici pur.	ʒ i.

M. Sig. For inunction at painful spot. Cover with cotton and rubber tissue.

Preservation of Solutions of Cocain.—JONAS of Brussels has experimented with solutions of cocain in distilled water, with and without the addition of various preservative agents, such as boric acid, glycerin, carbolic acid, etc., in different strengths. He finds the following solutions to remain permanently clear and unchanged:

1.	Cocain hydrochlor.	gr. iv
	Ac. carbolici cryst.	gr. ⅙
	Aq. dest.	ʒ iiss.
	M.	
2.	Cocain hydrochlor.	gr. iv
	Ac. salicylici	gr. ⅙
	Aq. dest.	ʒ iiss.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

CONSTIPATION CONSIDERED FROM THE STANDPOINT OF THE PROCTOLOGIST.[1]

BY A. B. COOKE, M.D.,
OF NASHVILLE, TENN.;
PROFESSOR OF ANATOMY AND CLINICAL LECTURER ON DISEASES OF THE RECTUM IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF NASHVILLE.

IT has occurred to me that a subject as trite and homely as constipation should not be approached in this presence without an introductory word of apology and explanation. I have not presumed to think that I have anything particularly new to offer; even to the furthest details the subject has been canvassed by other and abler writers. But in spite of its volume this portion of our literature has impressed me chiefly by reason of the vagueness of conception and indefiniteness of expression which characterize it. If I shall be able to contribute anything to a clearer and more systematic view of the subject my purpose will be fully accomplished.

It is more than unfortunate that confusion should exist in reference to this affection. From the standpoint of frequency no pathologic condition in the whole range of human ailments occupies so conspicuous a position; and from the standpoint of the rectal surgeon none is of such fundamental and far-reaching importance. Yet strange to say, judging from their published works, more than one of our most distinguished modern specialists have regarded it only of sufficient moment to be accorded casual mention in the discussion of diseases directly traceable to it. This to me is an anomalous position. It is scarcely conceivable that a proctologist could fail to realize the importance of the subject. Nor is it possible that there could be a reasonable question as to its falling properly within his province. To one without the fold the inference might not seem wholly unjustifiable that at least one specialty in the great brotherhood of medicine thinks less of prevention than of cure.

Broadly speaking, constipation is a disease in which, either directly or indirectly, the entire organism is implicated. It would manifestly be impossible, therefore, to attempt its consideration in all its phases; nor, indeed, is it desirable to do so. But the subject as set forth in our title presents a less hopeless undertaking and will, I trust, permit the development of practical, underlying principles both in essay and discussion.

In order to gain an intelligent comprehension of our subject, several preliminary items seem to me worthy a word of mention. In the first place much of the confusion in reference to constipation doubtless springs from lack of definite idea as to what the term means. Neither hard stools, nor dry stools, nor other kind of stools constitutes the disease. These expressions are merely descriptive of physical properties, and costiveness embraces them all. Constipation is something other and more. Correctly speaking, it is the condition of which costiveness is merely a symptom. Costiveness is not necessarily a disease, constipation always is, and, though usually associated, the former may exist without the latter. Again, constipation is a relative term. The line between the physiologic and the pathologic is not clearly drawn, and remarkable differences in individual habits may not be incompatible with ordinary health. With one person two movements of the bowels a day may be the normal; with another one in two days. And cases are on record by reliable observers in which not only days but weeks and even months elapsed without an evacuation and still the patients lived and flourished. So that neither the character of the stools nor the intervals between them can be properly regarded distinctive of the disease.

What, then, is constipation? The definitions given by the lexicographers lack that precision which should proceed from clear-cut ideas on the subject. In all I have consulted costiveness and infrequency of passages are employed as synonymous terms. If my conception of the disease is the true one, constipation may be broadly defined as *a diseased condition of the alimentary canal characterized by a modification of function which results in the pathologic retention of fecal matter*. With this definition for a foundation let us take a brief glance at the general subject, with reference especially to etiology. The causes of constipation may be conveniently arranged under separate headings, though it is to be understood that several, or possibly all, may be operative in any given case.

First. Causes springing from the violation of hygienic law. Under this head would come errors of diet and improper habits of life, to one or both of

[1] Read at the first annual meeting of the American Proctologic Society, held at Columbus, Ohio, June 7, 1899.

which sources, without a doubt, a large proportion of all cases may be traced. Chiefly notable in regard to diet are the two opposite extremes of habitually consuming food which leaves too much or too little residue. Evil results equally from both. Peristalsis is largely dependent on the mechanical irritation of the bowel contents. In the one case this would be interfered with by over-distention from the excessive accumulation of refuse material; in the other the requisite amount would be lacking. Many articles of diet have in themselves a constipating tendency. This applies more particularly, perhaps, to beverages of which tea and alcoholics are familiar examples.

In reference to habits of life, much of the greatest practical importance might be said. The significance of this factor in the production of constipation can scarcely be estimated. Yet it is a very open question whether it is fully appreciated even by the profession. The expression of the old physician to the effect that if his bowels moved naturally in the morning he felt sure he would not die that day, contains the germ of a profound truth. In the hurry and turmoil of modern life, particularly in the large centers, the attention to this function is made a matter of convenience and disease is the harvest of neglect.

Second. Defective innervation. This expresses itself either in (*a*) atonicity of the muscular coats of the intestines resulting in impairment of peristalsis; or (*b*) in decreased secretion. These conditions usually coexist and may be primary or consecutive. If the former, the constipation develops because of them. If the latter, they develop because of the already existing disease. The largest group of cases exemplifying these conditions is probably to be found in those of sedentary habits. The explanation is obvious. Paralysis is responsible for a smaller but more hopeless class of cases. In the first-mentioned class the origin of the trouble is purely functional, in the latter organic, yet the phenomena presented are identical in nature and the pathology involved different only in degree. Though mentioned as a separate cause, and rightly so, it is evident that defective innervation may be merely an effect of other causes. In fact, however brought about, it is a condition which may be said to exist to some extent in practically every case.

Third. Closely allied to the preceding, but entitled to separate classification, is the sluggishness of bowel function, often amounting to true constipation, met with in many diseased and debilitated states of the general health. Of these, anemia, laxness of the abdominal walls, obesity, diabetes, and great bodily weakness from any cause may be cited.

Fourth. A more obvious and familiar cause of constipation consists in the habitual use of purgative medicines. The pernicious effect of this practice requires no explanation nor emphasis. Yet its prevalence, already alarmingly widespread, is increasing at a rate which bids fair soon to make it universal. Fostered and encouraged by conscienceless advertisers, it belongs to the large and growing class of evils for which a venal press is responsible and for the suppression of which active measures are urgently demanded. Full redress is hardly possible short of legislative enactment. But the medical profession, by recognizing its duty and aggressively facing it could accomplish much. Bringing the issue nearer home, the proctologist, from the nature of his calling, is confronted by an obligation even greater. And that spirit of broad philanthropy which is the mark of the true physician demands of him all the labor and all the sacrifice that would be entailed by active warfare against this evil.

Fifth. Mechanical obstruction. This may occur at any point in the intestinal tract and vary widely both in pathology and degree. Though constipation is usually present, obstipation is the term more exactly descriptive of the resulting condition. Of the many causes operative under this head I stop for a word of comment upon only one. That true valves are present in the normal rectum modern investigation has left little room to doubt. But their significance as factors in the production of disease is only now being satisfactorily demonstrated. The ingenious methods employed and brilliant results obtained by Martin of Cleveland, in work along this line cannot fail to be convincing to those acquainted with them. Obstipation and hypertrophied valves are terms with which he has made us familiar. I have associated them in this connection in order to impress their relation and emphasize a fact. Other causes of mechanical obstruction, malformations, stricture, etc., readily suggest themselves, but must be passed with the mere allusion.

Sixth. Finally, in reference to etiology, I merely mention painful affections of the anus. This cause will be elaborated in the context.

Now to come to questions more immediately concerned in our present purpose. From the point of view of the proctologist this subject is of peculiar interest. The relations between constipation and diseases of the rectum are not only intimate but especially noteworthy in that either may be cause, effect, or both with reference to the other. I know of no other conditions in which such relationship is so clearly marked and so frequently manifest. With respect to rectal diseases, it is a rule to which there are no exceptions that every lesion in the entire

category may either be caused or seriously modified by constipation. With respect to constipation, though perhaps not so generally recognized, it is clearly demonstrable that rectal disease often stands to it in the light of causative factor. And either effect, once established, reacts powerfully and positively in intensifying the very condition which gave rise to it.

Considering constipation first in the active or causal rôle, the propositions stated are easy of verification. That venous congestion is the great underlying factor in the production of rectal diseases those who have given serious thought to the question will require no proof. The anatomical position and structure of the rectum, together with its peculiar function, render this to a greater or less extent its normal condition. Constipation augments it. A collection of feces in the colon or sigmoid acts as an impediment to the return blood current; and the dislodgment and extrusion of such accumulation, requiring as it does the cooperation of the powerful abdominal muscles, must result in converting passive into very active congestion, at the same time furnishing ready means for the infliction of traumatism. If the fecal mass, itself normally of firm consistence and more or less nodulated, contains a projecting foreign body, injury must attend its passage. Fissure, hemorrhoids, prolapsus, proctitis, ulceration, abscess and fistula are the more conspicuous lesions which may be traced directly to constipation and its coincident phenomena.

The present unsettled state of our knowledge as to the etiology of malignant growths permits no definite assertion in this connection. But discriminating observation with reference to their favorite sites justifies the assumption that mechanical irritation is a factor both constant and weighty. Statistics show that some 3 per cent. of all cases of cancer are located in the rectum. If friction may be admitted as a causative agency, the function of this organ, particularly when it has to do with costive stools, would render it an ideal situation for the development of this disease and the wonder is that the proportion is not even greater. To place malignant growths, therefore, in the list of rectal diseases for which constipation is, in a sense at least, responsible seems to be entirely in keeping with the most advanced thought upon the subject. The analogous nature of the gross lesions resulting from syphilitic and tubercular deposits in this locality would warrant a similar deduction in regard to them. But, attractive though the question is, it must be passed with these few comments.

Turning now to rectal diseases as a cause of constipation, two considerations under this head are worthy of special note. The first is pain. In those lesions situated about the extremity of the rectum pain is practically always a prominent symptom, and the passage of a stool of even normal size and consistence is an event contemplated with reluctance and dread. Remembering that defecation is in large measure a voluntary process, this is an item of greater import than might at first sight appear; and, while applicable, perhaps, with special force to children, so long as human nature shrinks from suffering, painful affections of the rectum and anus must be recognized in the etiology of this disease.

The second consideration is the influence of the reflexes from rectal lesions in the production of constipation. Here we enter upon less certain ground. Much is surmised, but very little really known about reflexes. Theories innumerable have been and are being advanced until it almost seems that every phenomenon not otherwise explicable is to be laid at their door. This tendency has worked to the disrepute of an etiological element which, though little understood, is yet both potent and pronounced. General discussion of the subject could scarcely be undertaken within the proper limits of a separate paper. But a few practical remarks with regard to the mechanism and manifestations of rectal reflexes seem absolutely necessary to elucidation of the idea before us.

The pouch of the rectum derives its chief nerve supply from the sympathetic system through the pelvic plexuses; the portion embraced by the sphincter muscles and the tissues of the anus almost entirely from the cerebrospinal system through the fourth sacral and internal pudic nerves. The former system, presiding over the functions of organic life, has to do largely with secretion and involuntary motion; the latter with the functions of animal life, sensation and voluntary motion. Whether the same is true of other localities or not, my observation has convinced me that rectal reflexes conform to at least one general rule, namely, that the reflex is expressed through the same system as that involved at the point of origin; in other words, that there is no transference of nerve impulse from sympathetic to cerebrospinal, and vice versa. So that a reflex originating in the sympathetic area, if referred to the intestinal tract, would express itself either in stimulation of the secretory apparatus or in increased peristalsis. Laxness would be the natural consequence.

On the other hand, a reflex originating in exposure or irritation of a nerve-fiber in the anal canal would manifest itself either in pathologic sensation, *i. e.*, pain, or in stimulation of a voluntary muscle. The latter is the point to which I would call special at-

tention. Any lesion of the terminal portion of the bowel, such, for instance, as a fissure or inflamed hemorrhoids, supplies the occasion of the reflex and the external sphincter is generally the muscle upon which it expends itself. The effect, if long continued, is irritability and hypertrophy of that muscle. When this occurs a mechanical impediment to defecation has been established and a condition of costiveness eventually merging into true constipation ensues.

Another cause for this condition of the sphincter and one more frequently in evidence, is neglect. When in response to peristalsis the fecal matter leaves the sigmoid and descends into the rectum a certain amount of irritation is excited by its presence and desire to go to stool is felt. The only barriers to immediate passage are the sphincter muscles by means of which Nature and the will operate to the welfare of the individual and in the interest of society. If the inclination is resisted, the feces are returned to their normal receptacle in the sigmoid flexure and the desire passes off not to return, most probably, for twenty-four hours. But as the accumulation increases from day to day reverse peristalsis does its work less perfectly and a portion of the feces remains in the rectum, where it becomes dry and hard from the absorption of its liquid contents and, impinging upon the delicate and sensitive mucosa covering the sphincters, excites these muscles to a state of chronic reflex contraction. In this way, just as from pain ful lesions of the anus, a condition of irritability and hypertrophy is produced. This is a cause of constipation which I am persuaded is not duly appreciated. Neglect, costiveness, hypertrophied sphincter, constipation is a sequence of events which obtains, doubtless, in many cases. And intelligent working comprehension of the subject requires that the process be recognized and each factor taken into account.

Before leaving the reflexes, as pertinent to the subject, I mention without comment the unique and rather remarkable experience of a prominent Nashville physician who has reported a number of cases of chronic constipation due to eye-strain and relieved by properly adjusted lenses.

The symptoms and diagnosis of constipation need no discussion before this body. One point, however, will bear mention for the sake of the emphasis it merits. Causes outside the rectum may beyond question be productive of the disease. But the effects of the disease itself are often such as to cloud its etiology by simulating other affections. Thus, auto-infection is probably in many cases responsible for the hepatic derangement, debility, defective innervation, etc., to which the constipation is credited. Therefore, the position cannot be considered an extreme one that this class of cases should without exception be subjected to thorough rectal examination.

The treatment of constipation might well afford the theme for a separate essay. Here I cannot hope to do more than indicate principles. Considering first the general subject, the essentials may be very concisely stated: If the diet is at fault, correct it. If the habits of life are improper, let them be modified. When these fundamentals have received attention medication may be thought of. Purgatives naturally suggest themselves first in this connection. Their proper field of application is a very limited one. It may be tersely stated: In the beginning to relieve the costive condition; afterward only when necessary for the same purpose. It is always to be borne in mind that purgatives as a class have proper reference only to the symptom, costiveness.

When the cause can be traced to defective innervation two principal indications are to be met in the treatment: First, reestablishment of the intestinal secretions; second, restoration of the muscular tone. For these purposes a great variety of therapeutic agents are at command. Wisely selected medicines are useful but not to be exclusively relied upon. In conjunction with them the various nonmedicinal agencies, such as methodical exercise, massage, and electricity are to be borne in mind and employed as indicated. Of course the general health will be looked after by the astute physician and any dyscrasia or cachexia receive due attention.

In the treatment of constipation resulting from rectal diseases, we have as the first indication, removal of the cause. But I wish especially to emphasize that this will not often be effective unless at the same time dilatation of the sphincters is practised. In no other way can the irritability and hypertrophy nearly always present be overcome. And, if this condition is not overcome, no line of treatment, however scientific and however faithfully applied, is likely to prove of more than temporary benefit. Fortunately, in the modern treatment of most rectal lesions dilatation, incidental or by design, is a routine preliminary; and to this fact unquestionably the great and lasting relief of the constipation which all of us have observed following operations, is in large measure attributable.

In conclusion, I wish to state my conviction that in a proportion of cases so large that I shall not venture to name it, constipation either originates in or is maintained by causes located in the distal ten inches of the intestinal tract. If I am correct in this, the notorious inadequacy of ordinary treatment is at once accounted for, and the duty of the proctologist in the premises becomes obvious.

ASTHENOPIC SYMPTOMS AND HEADACHE CAUSED BY THE MORE COMMON FORMS OF INTRANASAL DISEASE.[1]

BY CAROLUS M. COBB, M.D.,
OF LYNN, MASS.;
LARYNGOLOGIST TO THE LYNN HOSPITAL.

HEADACHE, from whatever cause it may arise, is one of the most frequent complaints with which the physician has to deal. It would certainly seem that more people suffer from this disease than formerly, or that they are less willing to bear the pain. The amount of headache medicine sold by druggists is something enormous, and the number of pairs of glasses worn to relieve headache is past finding out. Still the number of patients who suffer from this pain is steadily on the increase, and one patient relieved by any procedure brings many others, some of whom are relieved while others are not. Of the many causes which may produce the pain we have been inclined to think refractive errors the chief. This belief has arisen in part because our attention has been so often called to the part that such errors play in the production of headache, and in part by the brilliant cures that have been accomplished by the wearing of glasses. We have come almost to believe that all headaches as well as most other nervous diseases are caused by errors of refraction or muscular unbalance. The brilliant results I do not deny and I have had some as miraculous as any, but I do believe that the patients who can be relieved of pain or other obscure nervous symptoms by the glasses that are often prescribed need to have their nervous system reconstructed from the foundation. That we often overlook other causes in our zeal to find some ocular error which might produce the pain no one will deny, and I wish to call your attention to a few cases in which intranasal disease so closely simulated eye disease as to be very misleading. These cases illustrate the effect of the more common forms of intranasal diseases exclusive of diseases of the accessory sinuses.

CASE I.—Mrs. D., aged thirty-five years, consulted me in May, 1894. Her family history was good and the patient was well nourished and looked to be in good health. She complained of pain in the eyes and across the forehead, worse after using the eyes for near work. She was firmly convinced that the headache was due to the eyes. Tests showed vision in each eye to be normal. Muscular tests showed 6° manifest exophoria. She also had chronic hypertrophic rhinitis. The lower turbinates were considerably enlarged, but did not touch the septum.

She was anxious to have glasses as she was about to make her annual visit to her old home and she always suffered greatly during the railway journey of 500 miles. One statement that she made at her first visit was rather puzzling at the time, namely, that she suffered very much in making the journey out, but that on her return, six or eight weeks later, she was nearly free from discomfort. I satisfied both myself and my patient by supposing that the prolonged rest which she had enjoyed in the country had caused the change for the better. Prisms of 2° before each eye were ordered and on her return she reported that the glasses gave great relief during the first two or three weeks, but that latterly she had been unable to wear them at all. On examination the exophoria was found to have disappeared, and as she then did not need glasses she was advised to wear none.

This was in August, 1894. In November of the same year she called on me again, complaining of all the old symptoms. I then advised her to have the chronic rhinitis treated as the nasal condition was much worse than when I saw her in August. She came a few times for treatment and then ceased her visits and I did not see her again for two years. On her return in 1896 she had a long story to tell, the principal points being that she had given up the treatment of the chronic rhinitis by the advice of her family physician, who assured her that it could not be cured, and that her headaches were caused by cervical catarrh, which could be cured. I asked her if the cervical catarrh had been cured and she promptly and emphatically replied "no." She had consulted two other oculists and they had both advised partial tenotomy of the external recti. She had discovered that her eyes gave her trouble only in the fall and spring, during the period when her chronic rhinitis was worse and she was practically free from headache during the rest of the year. She is still in the same condition as she felt that she could not afford to continue treatment.

I have reported this case somewhat at length because it was so misleading not only to me but to others, and also for the light that it throws on many obscure cases of frontal headache, caused seemingly by muscular imbalance. I make it an invariable rule to examine the nose in cases of muscular insufficiency and it has proved a very satisfactory practice to me, and I have the records of many cases in which the patient has escaped the annoyance of wearing glasses by intranasal treatment.

CASE II.—A physician, aged thirty-three years. Family history good. He first came to me in 1895 suffering from hay fever. He had enlarged lower turbinates which touched the septum. He had also chronic ethmoiditis on the left side of many years' standing. He told me that he had had frontal headache during some part of every day for ten years and that he had often been confined to his room for several days at a time with excruciating pain over the eyes. To use his own expression he had taken everything that had been prescribed for him, from aconitia to Rochelle salts, and knew of nothing that

[1] Read before the Section on Laryngology of the American Medical Association at Columbus, Ohio, June 8, 1899.

had relieved him. He further added that during all this time no one had ever examined his nose.

His hay fever was easily controlled and later, during the fall, the lower turbinates were thoroughly cauterized. As soon as the burns were healed his headaches vanished and have not since returned. The ethmoiditis still continues but it is much better by reason of the better drainage.

It may be claimed that the pain in this case was due to the ethmoiditis, but it should not be forgotten that the ethmoiditis was one-sided and that the pain was as often on one side as the other, and that the pain was quickly relieved by the cauterization, while the ethmoiditis still exists after four years of improved drainage.

Another very common form of intranasal disease which causes headache is acute ethmoiditis. It is very often the case that an attack of acute rhinitis involves the anterior ethmoid cells and the inflammation remains in the cells for some time after the general attack has ceased. When these cells are involved the patient suffers from pain in and around the eye, which is often severe. The pain is so persistent and intense that the attending physician and the patient are fully persuaded that there is some serious disease of the eye. The following case is very characteristic of a large group:

Case III.—Mr. P., aged forty-three years, suffered from an attack of grip with a good deal of inflammation of the mucous membrane of the respiratory tract. During convalescence he complained of pain in the right frontal region, and around and in the right eye. I saw him in consultation and found the eye free from inflammation, pupil normal, and tension not raised. On examination of the nose the left side was found free from disease. On the right side the anterior ethmoid cells were inflamed and the mucous membrane covering the middle turbinate was red, swollen, and covered with a thin watery discharge. A spray containing cocain relieved the pain and swelling, and under measures directed to the relief of the ethmoiditis he made a good recovery.

This case is reported simply as a type of a very common affection. Often the diagnosis is far from easy, but an inspection of the nasal cavities under good illumination cannot fail to be an aid in clearing up the nature of the case.

Many patients have headache from a form of chronic rhinitis in which the discharge is not abundant, but rather viscid with a tendency to dry on the surface of the mucous membrane. The nasal breathing is not much obstructed except by the crusts, but the patients complain of a dull feeling of distress and discomfort across the bridge of the nose, extending upward across the brows, and at times giving rise to decided pain in the eyes. This condition of the nasal mucous membrane is distinctly different from atrophic rhinitis, but it is rather closely associated with uricacidemia and is often made worse by high living. I have seen many cases in which overindulgence in rich food made the nasal obstruction much worse in a few hours, and this result was so sure to follow any excess that the patients expected it. Measures directed to the systemic condition and regulation of the diet help these patients, but it is often necessary to treat the nasal disease by local applications.

Another form of intranasal disease that causes almost daily headache is hypertrophy of the posterior third of the middle turbinate. It is not at all a rare condition. The middle turbinate may touch the septum or approach it so closely that the narrow orifice is easily occluded by the congestion of the mucous membrane that follows any slight irritation. The headache from this condition is persistent and often severe and is only relieved by the removal of enough of the bony framework of the middle turbinate to provide a good space between that body and the septum. This operation quickly, and I believe permanently, cures the pain.

In this paper I have not attempted to discuss all the intranasal diseases which may cause headache, but have briefly alluded to some which seem to me to deserve more attention than they usually receive. I have no theory to offer to explain the production of headache by intranasal disease, but prefer to report the conditions as I have found them. At some future time we may be able to give a rational explanation of the connection between intranasal disease and headache, but as yet our knowledge of the subject is too incomplete to justify us in the indulgence of theories.

In conclusion I wish to emphasize the following points: First, headache may be and often is caused by intranasal disease; second, other disease aside from atrophic rhinitis, nasopharyngitis, affections of the accessory sinuses or the obstructive intranasal conditions may be the cause of headache; third, an examination of a patient suffering from headache is not complete unless the condition of the nasal cavities has been investigated.

THE INFRAPUBIC ROUTE IN SURGERY OF THE UTERUS AND ITS ADNEXA.[1]

By WILLIAM H. WATHEN, M.D.,
of Louisville, Ky.

Four years ago when Drs. Jacobs, Henrotin, and I read papers before this society in Baltimore, upon surgery of the uterus and its adnexa per vaginam,

[1] Read at the twenty-fourth annual meeting of the American Gynecological Society, held at Philadelphia, May 23, 24, and 25, 1899.

the subject was so thoroughly discussed by the Fellows, and all questions in favor of the infra- and suprapubic methods of dealing with diseases of these structures were so carefully considered, that I then believed there would practically be unanimity of opinion as to what cases should be assigned to each of these methods. I find, however, that notwithstanding the fact that this question has since then engaged the attention of the best specialists in this country and abroad, we are but little nearer a consensus of opinion than we were before that meeting, and the arguments against the vaginal method presented and answered upon that occasion are to-day urged with the same earnestness and honesty, although the experience of many men has demonstrated that facts do not justify such objections.

It will not be claimed that there are no diseases of the uterus or the pelvic structures that cannot be successfully treated by either the supra- or the infrapubic method, but nearly every objection to the latter is the result of a lack of observation or experience. I have recently read with no little degree of surprise arguments against vaginal hysterectomy in the discussion of a paper before a medical society in Philadelphia. Were not these men representative abdominal and pelvic surgeons I would not feel inclined to refer to their objections, for I would imagine that such opinions were unusual. This discussion leaves the conviction that many surgeons have not carefully studied the technic of hysterectomy, etc., per vaginam, but reproduce the theoretical arguments against such surgery that were advanced by the great surgeons of Paris in their opposition to the late Peán when he first emphasized his success in this kind of work. If we will read the arguments of the men at that time, and then the discussions against the vaginal method offered now, we will see the striking similarity and the same evidence of the theoretical character. But I dare say that had all our American surgeons practically tested this method, as did Segond, Richelot, Pozzi, and others, they would have changed their opinions just as these men did, and would have learned that the objections they had supposed to exist are not real.

An experienced surgeon by the infrapubic route is surprised at surgeons who oppose this method because of their repeated insistence that by the abdominal route one can see the structures with which he deals, but cannot see the structures encountered by the vaginal route, for they have neither performed the operation correctly nor seen it correctly performed. Any person who has often operated by both methods will tell you that, with few exceptions, nearly every structure treated from below is brought in view before the knife or the scissors is applied; and even in enucleation of pus tubes and ovaries, if we first bisect the uterus the eye can guide the finger as well as by any other method, and the finger can explore to the pelvic brim with its trained sense of touch. Nor will the statement that we must necessarily wound the intestines in infrapubic operations more frequently than in suprapubic operations bear the test of intelligent experience.

I have performed vaginal hysterectomy since 1888, and during the last few years have treated every diseased condition of the pelvis by this method, when indicated, if the consent of the patient could be obtained. During these eleven years I have never wounded the bowel or ureter; but I have wounded the bowel several times in performing abdominal section. I claim no special excellence of technic in avoiding injury to these structures, but contend that every well-trained surgeon can obtain the same degree of perfection in results if he will persist in his efforts.

One thing that may have prevented the more general adoption of the vaginal method, and may have caused people to oppose it, is the belief that the technic is so complicated that it is difficult to do the work without committing the sins above mentioned. I can understand why this belief exists to a greater extent than otherwise, in that too many surgeons use an unnecessary multiplicity of instruments, and especially of retractors, because these appliances, with few exceptions, are of no practical use and often complicate the operation.

In my early hysterectomy operations I was prone to adopt the methods of my predecessors without considering whether there might probably be an improved technic in some details. In many cases in hysterectomy no retractor is needed, and seldom more than one, and by dispensing with them the operation may be performed more rapidly, more successfully, and with less danger of wounding adjacent organs, for the *fingers* are the best retractors that can be used. By this method, if we bisect the uterus there is usually no difficulty in seeing the tissues before the knife or the scissors is applied; but if we cannot the finger may be carried in advance of the cutting instruments, in contact with the uterus or diseased tissues, thereby preventing wounding the bladder, the intestines or the ureters. I have for several years observed this technic, and the more experience I have the more I feel justified in insisting upon its superiority. Every part of the vaginal wall and the cervix may often be exposed by the fingers and seen as plainly as tissues outside the body.

I can readily see that there may be an objection to vaginal hysterectomy in some instances, and also to dispensing with retractors, if the uterus is not bisected; and just here is an excuse for the opposition urged against vaginal hysterectomy by surgeons who tell us of the dangers of wounding vital structures. It is not possible to see all the tissues involved in removing pus-tubes and applying clamps if this is done before the uterus is bisected, because these structures are then high in the pelvis and mainly hidden from view. There is no danger, however, of wounding anything but the uterus during the process of bisection; and after the organ is divided each side may be separately pulled outside the vulva, adhesions treated as they present, and the broad ligament, including the ovaries and tubes, clamped externally from above, in full view. There is no danger of wounding the intestines in separating adhesions from the uterus, for it is exceptional that the bowel is firmly adherent to this organ, and if so, by hugging the uterus closely it is easily separated without danger of structural injury; and omental adhesions are of no consequence.

While I do not believe the uterus is an important organ after the removal of the ovaries and tubes, still there are many cases in which it might be well to leave it, or in which the patient will not consent to its removal, and her convalescence may not, because of this fact, be interfered with, and she may remain well. In these cases I have had but little difficulty in removing the ovaries and tubes through a vaginal incision into Douglas' pouch, going behind the ureters and the uterine arteries. If the incision is made close to the uterus no vaginal arterial branches will be wounded and hemorrhage will be of no consequence, nor will there usually be much trouble in separating adhesions and bringing the ovaries and tubes into the vagina. They can then be removed with almost as much perfection as they can through the abdominal wound.

In this operation retractors are absolutely in the way, and no one can do perfect work of this kind who continues their use. And in this connection we may show the fallacy in the arguments against the infrapubic method offered by persons who claim it is not conservative, for it is impossible to perform more conservative surgery upon any part of the body, or by any known method, where the operation could in any sense be considered a capital operation.

There is no danger in opening Douglas' pouch after the vagina has been made aseptic, and the uterus likewise, by thorough curettage, etc.; and when the ovaries and tubes are brought into the vagina, if not diseased, they may be returned without injury, but if diseased not enough to justify removal they may be treated by any approved method, returned to their place, and the vaginal incision immediately closed. The operation performed after this fashion is of so little significance that it is not more dangerous than the operation for curetting and for lacerated cervix, and the patient, having no elevation of temperature or rapidity of pulse, is able to leave her bed at any time the surgeon will permit her to do so.

If there is doubt as to whether the ovaries and tubes are diseased sufficiently to justify the removal of one or both adnexa we should first carefully examine these organs through an opening into Douglas' pouch, and if neither should be removed, or if one should be removed only, be governed by the indications.

Nothing more could be accomplished by the suprapubic method, and by that method the abdominal wound in itself should confine the patient to bed for not less than two weeks, and require an abdominal support for one year; and in the vaginal method of exploration there is no danger of hernia or post-operative intestinal adhesions, while there is danger in the abdominal method, whether any organs are removed or adhesions separated. This is proven by observation in operations for ventral hernia following celiotomy, and we are always watchful in our incision to prevent wounding an intestine adherent to the abdominal wound.

When but one ovary and tube should be removed, let it be as a result of any kind of injury—pyosalpinx, ovarian abscess, tuberculosis, extra-uterine pregnancy, etc.—the other side may serve just as useful purpose as before the operation, and many of these women have afterward borne children without trouble. While there may be a few cases where the operation could not be completed without hysterectomy or abdominal section, I have not met with such a case, and I have not performed the suprapubic operation for extra-uterine pregnancy for nearly four years, but have performed about thirty through the vagina, each patient making an uninterrupted recovery. When one or both of the adnexa are removed per vaginam the convalescence is so universally uninterrupted that we learn to believe that every patient will make a prompt recovery. Of course it would not be the correct thing to attempt to complete an operation for extra-uterine pregnancy in intraperitoneal rupture with a large accumulation of blood in the abdominal cavity that could not be drained away; but in this condition there are times when vaginal incision into Douglas' pouch, and clamping the tube at the point of rupture, may save the life of the woman by promptly controlling hemorrhage until she can be resuscitated sufficiently to

resist the dangers of a celiotomy. In some of these cases the shock is so great that an abdominal section cannot be performed until the patient rallies, and often just as the pulse begins to become well perceptible secondary bleeding may cause death. A clamp may be applied through the vaginal incision without the administration of chloroform if the patient is not able to take an anesthetic, and removed at the time of the celiotomy.

Having first insisted at the meeting in Baltimore that in operations per vaginam, when septic matter in the pelvis is held there by an over layer of intestines agglutinated by inflammatory exudations, that these adhesions should never be disturbed if it can be avoided, and that experience has taught that they usually cause no trouble, I will not dwell specially on that point to-day. Nature is always conservative, and in protecting the abdominal cavity from the poisons in the pelvis she usually does so after a systematic fashion that may cause no trouble if the adherent intestines are not separated, and this protecting roof should not be disturbed, either in vaginal incision or in vaginal hysterectomy. No experienced celiotomist will contend that it is not dangerous to remove a large accumulation of pus, hemmed in after this fashion, through the abdominal incision, for while it may be sterile in one instance it may be virulent in another, and we never know that we can positively prevent soiling the healthy peritoneum; but if we succeed in separating the adhesions without wounding an intestine or causing local or general sepsis, it is impossible to prevent post-operative irregular adhesions more dangerous to health and life than would have been the agglutinated intestines left undisturbed in an operation per vaginam. Patients in whom there is an extensive accumulation of pus, with tissues thoroughly septic and softened, may symptomatically recover by incision and drainage without the removal of any organs, and I have seen many of these who afterward did not complain of pelvic trouble. This is applicable in accumulations of pus following abortion or labor; but in cases of local sepsis at such times the formation of pus may be prevented by prompt vaginal incision, opening the folds of the broad ligament, or separating pelvic adhesions, and lightly packing with iodoform gauze, so as to separate and keep apart the infected surfaces. If these cases could be seen at the beginning of sepsis the results would be good, but unfortunately we are not often called until the disease has made too much headway and pus has accumulated.

In both vaginal hysterectomy and vaginal incision for removal of tubes and ovaries, or for other purposes, we should apply just as little gauze as will meet the demands, being careful to cover the ends of the clamps to protect the intestines against subsequent injury. Too much gauze packing is painful, keeps the vaginoperitoneal opening too widely distended, and does not drain well. But little iodoform gauze should be used, for it has often caused intoxication, and has occasionally caused death.

To insure perfect drainage it is best to place a gum tube in the vagina with the end in the lower part of the vaginal incision and against the gauze packing. The tube should be used until after the gauze has been removed, and until the opening between the vagina and peritoneum has closed so as to *positively* resist the passage of water in vaginal irrigation. I do not believe it is best to leave the gauze packing for a week or ten days, as has been done, but I remove it gradually, beginning on the third day and taking out the last piece on the fifth or sixth day.

I have never observed that the length of the vagina has been materially altered, or that the secretion has been especially interfered with. If an appendix is sufficiently diseased to justify its removal, then the direct symptoms will enable us to make a diagnosis and guide us in the selection of the best method in operating. The relatively delayed convalescence, the abdominal incision, and the danger of hernia must be accepted in a minor degree as objections to the suprapubic route in selecting that method instead of the infrapubic route.

THE SERUM-TREATMENT AND ITS RESULTS.

By HERMANN M. BIGGS, M.D.,
OF NEW YORK.

(Concluded from page 105.)

Pneumonia.—There is no disease, excepting possibly tuberculosis, which is more fatal and in which a specific preventative and curative method of treatment is more to be desired than in pneumonia. The records of the New York City Health Department show that the deaths ascribed to pneumonia of different varieties number on the average about 5000 a year and are only exceeded by those due to the tubercular diseases.

Since 1884, when A. Fränkel first separated the pneumococcus in fresh culture, numerous bacteriologists have endeavored to produce immunity against the processes caused by this organism. In animals many methods have been employed to obtain this result with varying success.

The technic of experimentation with the pneumococcus has always offered unusual bacteriological difficulties and these have deterred many experimentors and have no doubt delayed the accomplish-

ment of the desired result, but the stimulus given by the success in obtaining antitoxic serums for tetanus and diphtheria has induced in recent years renewed efforts to obtain a curative serum for pneumonia in man.

The Klemperer brothers in 1891 reported somewhat favorable results from the treatment of six cases of pneumonia by an antipneumotoxin precipitated from the blood of immune rabbits; Jansen later reported apparently favorable results in ten cases of pneumonia treated by the injection of the serum of immune rabbits, and in 1893 Lara and Botzolo recorded what they regarded as encouraging results. In 1896 DeRenzi recorded the results obtained from the treatment of ten cases of pneumonia with antitoxic serum, and while all recovered the author felt unwilling to say they might not have recovered without the use of the serum. In 1897 Weisbacker reported five cases treated by injections of serum obtained from patients convalescent from this disease, and while the objective symptoms do not seem to have been much affected by the treatment the subjective feeling of relief is said to have been marked in all and recovery in all occurred. Washburn immunized a pony and with the serum thus obtained treated two cases successfully. He describes a method for determining the antitoxic power of the serum employed. Parre reports the results of experiments made with serum obtained from an ass, a cow, and rabbits thus immunized, in which he found the serum of the ass most efficacious. He reported twenty-two cases of pneumonia treated with this serum, with two deaths, these two patients being practically moribund when the serum was administered. In a later article he states that he is using the serum systematically, and that when given in 50 c. c. doses early in the disease, crisis and recovery invariably followed.

Ughetti of the University of Cantania and Cantieri, Director of the Medical Clinic at Sienna, express favorable opinions as to the efficacy of the serum prepared by Parre, while Massolongo of Verona concludes a careful and minutely detailed report as follows: "My impression as to the value of the antipneumococcus serum is that it is more efficacious in the treatment of pneumonia than any other agent we possess. These first experiments of mine convince me that from the DeRenzi and Parre serum we can obtain a clearly defined action on the pneumonic process, which it influences directly." Nine other clinicians have recorded similar experiences during the last year and have communicated the results to the Sero-Therapeutic Institute at Naples, where the serum is prepared.

Some experiments instituted along this line in the laboratories of the Department of Health, while still incomplete, give encouragement to hope for ultimately successful results. It is undoubtedly possible to confer upon animals (horses being employed in these experiments) a high degree of immunity to virulent cultures of the pneumococcus and the serum derived from these animals in very small amounts will protect rabbits from many times a fatal dose, when administered before the inoculation of virulent cultures of pneumococcus. The controls invariably die from the injection of $\frac{1}{1000}$ part of the dose administered to the protected rabbits. A larger quantity of the serum is required to protect animals when the culture is administered at the same time or previous to the administration of the serum, but even then, if the administration of the serum is not delayed for too long a period, the rabbits still live.

The conditions obtaining in such experiments are quite unlike those ordinarily existing in pneumonia in the human being, as pneumococcus septicemia is ultimately produced by the inoculations and this does not occur, as a rule, in lobar pneumonia in human beings except in severe cases and late in the disease. The animals, in these experiments, which showed a general septicemia at the time of the administration of the serum invariably died, but lived longer than the controls. Those animals which did not show a general septicemia at the time of the serum injection have in part lived and in part died. Successive doses also seem sometimes to save animals which would otherwise have perished.

The practical results obtained in the treatment of pneumonia in the human being with this serum are indecisive. The experimental results, however, are striking and justify a hope that better results may be later obtained with improved methods, and a serum of higher grade.

It is undoubtedly important in this disease as in the other infectious diseases in which the serum treatment has been successfully employed, that the remedy should be administered at an early stage of the disease.

It seems quite within the range of possibility that the next great achievement of serum therapeutics will be in the production of an efficient antipneumococcus serum, and if this should be obtained all of the previous successes in this department of medicine would in practical importance be far surpassed.

Epidemic Cholera.—Encouraging results have been obtained in both the preventative and curative treatment of epidemic cholera. Extensive investigations were carried on by Haffkine under the supervision of the English Government in India, in regard to the use of preventive inoculations for cholera. More than 100,000 persons are reported to

have been subjected to these inoculations, the material used in them being the dead cultures of the cholera bacillus. The inoculations in themselves are harmless although they are followed by some local and general reaction, which is, however, of short duration. To confer complete immunity Haffkine's method requires two inoculations with an interval of about eight days between them.

The following may be considered as indicating fairly the general results obtained from these inoculations:

The managers of certain tea estates, among the coolies of which the inoculations were carried on, reported that out of 29,000 employed on the estates, 7507 had been subjected to the inoculations; among these 63 cases of cholera afterward occurred, with 28 deaths—the admissions thus being 8.39, and the death-rate 3.73 per 1000. Among 21,443 coolies not inoculated, in the same gardens, there were 260 admissions, with 150 deaths from cholera, showing an admission-rate of 12.13, and a death-rate of 7 per 1000, or about twice the rate among the inoculated. The majority of those inoculated were only subjected to one inoculation with the weaker virus, which according to Haffkine, gives only partial results. In a small set of experiments carried on by Surgeon Hare after Haffkine's departure, 196 out of 355 coolies on one estate were inoculated; 4 of the inoculated coolies were seized with cholera and died Among those not inoculated there were 34 cases and 30 deaths during the same period. These figures give admission- and death-rate among the inoculated coolies as 20.4 per 1000, while among the non-inoculated coolies the admission-rate was 213.8, and the death-rate 188.7 per 1000. It is also reported that in a later series even better results were obtained.

As to the curative value of the anticholera serum we may refer to the experiments of Kitisato, which show that in the Hirdo Cholera Hospital the mortality from cholera was apparently reduced by 20 per cent. by the use of the serum, and that in early cases—that is, those treated within the first twelve hours of the disease, the mortality was reduced to about 14 per cent. instead of the average 70 per cent. among those treated in some other manner. Experimentally it has been shown that the serum protects guinea-pigs from the results of the inoculation of many times the fatal dose of a cholera culture, when injected simultaneously into the peritoneal cavity. When injected subcutaneously, somewhat larger quantities of serum were required to confer protection; but this was still obtained if the curative injection was not made too long after the infection.

Koch said to the writer two years ago, with relation to the protective inoculations against cholera, that he had no doubt that in any future outbreaks of cholera in Europe or in America the disease would be promptly controlled through the use of immunizing injections, and that a maritime quarantine against this disease would be no longer required, as persons exposed on shipboard would be immunized and thus protected.

Bubonic Plague.—Still more encouraging results have been obtained in the preventative and curative treatment of the bubonic plague. The method adopted in testing the treatment consisted in the selection of a group of persons living under similar conditions, inoculating a portion of this group and leaving the remainder uninoculated, and then noting the incidence of the disease in the two groups.

At Kirkee, where plague broke out among the artillery, an excellent opportunity with these conditions presented itself, and the results were as follows: Among 875 non-inoculated men there were 133 cases of plague with 102 deaths, while among 667 inoculated, there were 32 cases with 18 deaths. The figures are strikingly in favor of the inoculated, for if the inoculated had had proportionately the same number of deaths as the non inoculated, they would have had 89 deaths instead of 18, a difference of 71 deaths, a reduction of nearly 80 per cent. In Damann the results were equally good. In this small town Haffkine inoculated altogether 2297 persons. Of 6933 persons in the town who were not inoculated 1482 died, *viz.*, 24.6 per cent., while of the 2297 inoculated, only 36 died, or 1.6 per cent., instead of 332, which would have been the number had the deaths been in the same proportion as among the non-inoculated. In this series there was a reduction of 89.2 per cent. To meet objectors Haffkine and Lyons point out that with such results and so high a proportion of the inoculated to the rest of the inhabitants (2297 to 6933) it is impossible that the inoculated represented the upper or any particular class of the population to which their reduced death-rate could be ascribed. A notable example is given in theParsee Community which consisted of 306 persons, of whom 277 were inoculated, leaving only 29 uninoculated. In the 29 uninoculated there were 4 deaths from plague, or a mortality of 13.8 per cent., while among the 277 inoculated there were 8 attacks with only 1 death, which occurred in a woman ill of plague before the inoculation. Counting this death the mortality in the inoculated was 0.36 per cent. or 38.3 times lower than in the uninoculated. Again,in Lanowli, where inoculations were carried out in two infected and isolated centers, 422 non-inoculated had 68 cases and 48 deaths, and 293 inoculated had 5 deaths. If the deaths among the

inoculated had been proportionately as high as among the non-inoculated there would have been 33 deaths instead of 5, a difference of 28 deaths, or 84 per cent.

The observations in Bombay and Mora are less instructive, because they are not comparative; still they are interesting, and confirmatory of the favorable influence of the inoculations. In Bombay 8142 persons were inoculated, and among this number 18 were attacked with plague, 16 of whom recovered and 2 died. The 2 fatal cases were ill with plague at the time of inoculation. In Mora Kolaba, a small place in which plague appeared, 419 of the inhabitants were inoculated; 4 of these were attacked, but all recovered. A careful analysis of the results of the inoculation seems to show that the efficacy of the prophylactic depends on the virulence of the bacillus from which the lymph is prepared, and on the dose and its power of producing a well-marked febrile reaction, and that it is more effective in preventing deaths than attacks.

Typhoid Fever.—Wright and Semple have employed Haffkine's method of vaccination against cholera in the prophylaxis of typhoid fever. The vaccines are made from agar cultures of typhoid bacilli which have been grown for twenty-four hours in the incubator. Cultures thus obtained are emulsified by the addition of measured quantities of sterile broth. The resulting emulsion is then drawn up into a series of sterile and calibrated glass pipettes, the capillary ends of which are sealed in the flame so as to form vaccine capsules. The capsules are then placed in a beaker of cold water which is brought to a temperature of 60° C. and kept at that temperature for five minutes. The vaccines are inoculated into the flank. The strength of a typhoid vaccine will obviously be determined (1) by the number of bacilli which it contains, (2) by the virulence of these bacilli. In their later experiments they employed a typhoid culture of such strength that one fourth tube of twenty-four hour culture constituted a lethal dose for a guinea-pig of 350 to 400 grams when hypodermically injected. The quantities of this culture used for antityphoid vaccinations varied from one twenty-fifth to one-fourth of a tube. The latter quantity (*i.e.*, the quantity which, if injected *alive*, would have proved fatal to a 350 gram guinea-pig) constitutes a somewhat severe dose for a man.

Clinical Symptoms.—When the smaller doses (one-twenty-fifth to one-sixth of a tube) are used the symptoms are comparatively slight. The local symptoms consist in a little tenderness; the constitutional symptoms in a subjective feeling of chilliness, which comes on about two or three hours after the inoculation of the vaccine; further, in a very slight rise of temperature and a little restlessness at night. The symptoms have quite passed off in twenty-four hours. With larger doses the symptoms are all more severe. There is considerable local tenderness and inflammation, which disappear after forty-eight hours. The constitutional symptoms, consisting in some degree of faintness and collapse, begin to manifest themselves generally in two to three hours. In 4 out of 11 cases inoculated with the larger doses faintness and nausea (resulting in 1 case in vomiting) were already well marked after three hours. In the other 7 cases these symptoms supervened later. Only 3 out of the 11 cases were able to put in an appearance at dinner. A good deal of fever was developed in all cases, and sleep was disturbed. By the next day 8 out of the 11 persons treated returned to their normal condition of health; 3 of the 11 looked somewhat shaken in health for some weeks after. Calcium chlorid (45 to 60 grains) was administered with a view to prevent a decrease of blood-coagulability. Examined by the Widal-test the results showed in the most evident manner that the blood of patients who have submitted themselves to an antityphoid inoculation becomes in some measure poisonous to the typhoid bacillus by giving the reaction of immobilization and agglutinization, and it may be inferred that these persons are immunized against typhoid fever. This conclusion, however, cannot be regarded as assured until we are in a position satisfactorily to account for the fact that typhoid-fever patients and Malta-fever monkeys who succumb to these diseases show the specific sedimentation reaction in exactly the same way as the typhoid-fever patients and Malta-fever monkeys who recover from these diseases. (Wright and Semple.)

With regard to the danger associated with antityphoid vaccinations, Wright and Semple say: "When we appreciate that the bacteria which are employed in these vaccinations are *dead* bacteria, and that they are incapable of generating new poison in the system, it will be obvious that the injection of small and measured quantities of these dead bacterial cultivations involves no more risk to life or health than the injection of a medicinal one of morphin. That there is no unknown factor of risk in the case of the injection of bacterial toxins will be evident when we consider that Haffkine has performed nearly 100,000 anticholera inoculations without a death, and as far as we can learn without the supervention of a single serious symptom.

"Although there are no facts as yet upon which to base definite conclusions, it is legitimate to judge, from the extremely slow disappearance of the per-

fectly comparable 'sedimentation' power, which is acquired by undergoing an attack of typhoid, there is every reason to hope that the immunity which is conferred by these vaccines may persist for a considerable number of years. If it does so it will obviously suffice to carry a young adult over the period of his extreme susceptibility."

As to the sphere of application of the prepared antityphoid vaccinations, they suggest, since these vaccinations are unattended with risk, that it would be expedient for every one who is likely to be frequently exposed to the risk of typhoid infection to undergo the vaccination. In particular this would appear to be expedient in the case of young soldiers going to typhoid-infected districts, to nurses in attendance upon typhoid patients, and to persons who are living in any district which is being visited by an epidemic of typhoid.

Semple later reports as regards the value of these prophylactic inoculations, that out of 84 persons vaccinated against typhoid during an epidemic, not one contracted the disease, while of 120 not vaccinated, under the same conditions 16 were attacked by it.

Sanarelli's Anti-amarylic Serum for the Treatment of Yellow Fever.—It is claimed that this serum is germicidal to the microbe causing yellow fever, while it is impotent against the poisoning produced by this organism. Successful results, it is said, can only be obtained by the injection of the anti-amarylic serum very early in the course of the disease (before the microbe has become firmly lodged and has produced diffuse poisoning), then the yellow-fever bacillus is destroyed, and the disease is cut short.

Sanarelli says that good results are difficult to obtain if the treatment be applied when the disease is already advanced after the amarylic poison has largely accumulated in the organism and has already induced grave anatomical and functional changes which the serum is powerless to counteract, and which of themselves suffice to cause death. The application of the serum, therefore, must be confined to the first period of the malady.

"The serum, itself, is in no respect harmful and can be administered in the desired quantity up to the moment when all hope of success is not yet definitely abandoned. The beginning dose is 20 c.c., and if this is followed by no appreciable improvement, a second, third, or further doses may be administered according to the patient's general condition. Injections may be made subcutaneously in the thigh or nates, but in urgent cases it is preferable to introduce the serum directly into a vein of the forearm."

Wasdin, who employed it in several cases in Louisiana says that in one case there was a very prompt reaction, evidenced by the rise of temperature and pulse, and the great redness of the face and skin of the body. This was followed by a cessation of all pain in a few hours and a fall of temperature and pulse to a point lower than before administration. The second and third injection showed less marked reaction. The exhibition of the serum produced free secretion of a non-albuminous urine, some ptyalism, and free perspiration, but Wasdin thinks the patient would have done equally well with other medication. The second case he thinks would have undoubtedly done as well without any medication.

"The influence of the serum upon the vasoconstrictors was very pronounced, causing mental and physical suffering. At first the urine was free and always non-albuminous, but on the second day became diminished although the skin acted freely. A rash was produced, partly urticarial and partly erythematous. The reaction in this second case was excessive, the temperature rising to 104°. The doses administered were 10 c. c. each; the full dose advised was 20 c. c." Wasdin felt satisfied that the larger dose would have caused much alarm and probably harm.

Cases seen in this epidemic were so mild that he did not feel justified in injecting a greater number of persons and subjecting them to the risks attendant upon the use of a remedy with the results of which he was unacquainted.

Streptococcus Infections.—Infections due to the streptococcus have long been the subject of experimental investigations and many bacteriologists have endeavored to produce a curative serum for their treatment. The difficulties in the way of success are numerous and have thus far been only to a limited extent overcome.

It has been shown by many experimentors that it is possible to immunize animals by the inoculation of rapidly increasing doses of living and virulent streptococcus cultures, so that their serum finally possesses the power to protect rabbits under special conditions against infection from many times the fatal dose of the special streptococcus used for the inoculations. The protective power of this serum is specific. It does not exist in normal serum or in the serum of animals immunized against any other organism. Unfortunately, however, this serum more rapidly loses this characteristic power than tetanus or diphtheria antitoxic serum, and often is practically inoperative six weeks after its withdrawal. It has been further shown that this serum does not necessarily confer immunity to any other streptococcus than the special one which has been employed in the original inoculations. It may be almost powerless

against some pathogenic streptococci, while it is strongly protective against others. Like other antitoxic serums it produces its most marked effects when introduced before the inoculation of the streptococcus cultures. If introduced at the same time as the culture it is more active when injected in the same area with the cultures than when introduced on the opposite side of the body of the animal. A series of experimental investigations on the production of this serum has been carried on in the laboratories of the Department of Health for more than three years, and the conclusions which have been reached by other experimentors have been fully verified.

The results obtained from the practical use of antistreptococcus serum in septic infections in the human being have been of the most conflicting nature. Some observers have reported excellent results in a number of cases, while many others have found the serum almost valueless. The practical results are fully in accord with the conclusions deduced from the experimental investigations. Undoubtedly in some instances the serum has proved of value when used in the human being. These were cases in which the serum employed did exercise a protective influence against the special organism producing the infection, and in which the infection was probably not of a very intense nature and a general streptococcus septicemia did not exist.

In the majority of instances in which it has been used clinically it probably has not been of any value. This result should be expected for a number of reasons. In the first place many of the preparations of serum had undoubtedly lost such power as they may have originally possessed before they were used for the treatment of human beings; second, the protective power originally was not sufficient in the doses in which it was employed to have been of much value even if introduced when fresh; third, there is little evidence to show that this serum is of much value when a severe general septicemic condition exists; fourth, in many instances the infection has been due to some pathogenic streptococcus different from that employed in the inoculation of animals from which the serum was obtained and against which the serum would have no power; fifth, many of the cases in which it has been employed were not cases of streptococcus infection at all, but were infections due to entirely different organisms, as the staphylococcus, colon bacillus, pneumococcus, etc.

It may, therefore, be assumed, from what has been said, that at present the practical value of this serum is limited. This feeling has been so strong in the Department of Health that it has never been considered wise to issue it for general use, and while it can be obtained by public institutions or private physicians in this city on application for the treatment of cases of septic infection on condition that the results obtained are reported to the Department of Health, yet its use has never been recommended or encouraged because it was felt that the experimental results did not justify such action. It should be added, further, that these conclusions do not apply solely to the preparation produced in the laboratories of the Department of Health, but to all preparations which have thus far been tried experimentally. The experience of the writer in the use of this serum, and the reports which have been received from those who have employed the serum entirely confirm these conclusions. It does not follow, however, that we may not ultimately obtain a preparation which will have definite practical value.

It should be said in passing that a large proportion of the cases of infection supposed to be due to the streptococcus are on bacteriological examination shown to be due to other organisms. In five of the last six cases treated with the serum produced in the laboratories of the Department of Health bacteriological examinations were made, and in three the infection was found to be due to other germs.

I have not taken up the consideration of several diseases of animals in which remarkable results have been obtained, especially in the preventive treatment, *i.e.*, rabies, tetanus, anthrax, and rinderpest, because of the lack of time, and nothing of special importance has been recently added to our knowledge of the three first, while the work on rinderpest, although apparently successful, is still in the experimental stage.

It may be useful to consider just for a moment, finally, what has been thus far accomplished in the preventive and curative treatment of various infectious diseases by the use of substances of bacterial origin.

Leprosy and tuberculosis may be, in my opinion, entirely thrown out of consideration. There is no satisfactory evidence as yet adduced to show that in either of these diseases anything has been accomplished either in the prevention or cure. In three diseases in the human being, rabies, tetanus, and diphtheria, and anthrax and probably rinderpest in animals, we have perfectly efficient means for conferring immunity which are practically available. It further seems probable that immunity may be also conferred to snake venom. There is also very strong evidence of the practical value of the protective inoculations against cholera and plague. All the work with reference to typhoid fever, streptococcus infec-

tions, and pneumonia must be considered as only in the experimental stage.

When the curative treatment is considered, in only one disease can it be said that serum-therapy has afforded us a perfectly satisfactory method of treatment, that is in diphtheria. In all of the others all of the practical problems remain as yet unsolved, but in some there is a reasonable prospect of an early solution.

MEDICAL PROGRESS.

Subcutaneous Rupture of a Hydrocele.—MACKENZIE (*Brit. Med. Jour.*, May 27, 1899) reports an instance of a rather rare accident, the rupture subcutaneously of a recurrent hydrocele. It was associated with a scrotal hernia, for which a truss was worn. The patient, a plasterer, aged 48 years, was reaching below his scaffold, and as the truss pressed upon the top of the hydrocele, he felt something burst. There was no great pain. There was swelling of the penis, but this disappeared the following day under a cold application and rest in bed. The fluid reaccumulated, but not so rapidly as it did after tapping.

Protrusion of the Intestines in a New-born Babe.—BELL (*Lancet*, June 3, 1899) was called upon to treat a Chinese baby in whom two feet of the intestines protruded from a rent in the much dilated and thinned base of the umbilical cord. The intestine was washed and returned to the abdominal cavity, and the cord was ligated, and cut off. This ligature slipped in a few hours, and the intestines again escaped. They were returned a second time and the rent was sutured. There was no peritonitis, and the wound healed firmly, although cicatrization was not complete until the twenty-first day.

Dilatation of the Anus for Vesical Pain.—GUEPIN (*Rev. de Therap. Medico-Chirurg.*, June 1, 1899) states that anal dilatation is a palliative measure which ought not to be omitted from the treatment of incurable, painful, and spasmodic affections of the ureters and bladder. It is also a proper preliminary measure in certain major operations on the urinary tract.

THERAPEUTIC NOTES.

Muscular Development as a Radical Cure of Hernia.—WARDEN (*Lancet*, June 10, 1899) says that many cases of hernia can be permanently cured by the systematic development of the abdominal muscles. An examination of the external rings of an athlete will show one how firm and small they are, and how much less is the cough impulse, than that felt in an ordinarily muscular person. The advice that is often given to a patient whose hernia is treated by a truss, is to avoid muscular exertion. Following these directions his abdominal walls become flabby, whereas if he takes more exercise than before they will be growing stronger. Warden has seen a great change in the ring, after three- or six-months' regular exercise. He proposes three forms of exercise as especially adopted to such cases: (1) In dorsal decubitus, with the hands at the sides, the patient is to raise his body from a lying to a sitting posture. (2) In dorsal decubitus, let him raise both legs from a horizontal to a vertical position. (3) Let exercise No. 1 be performed in such a manner that the body sweeps toward one side before coming to an upright position, describing a curve and bringing into play the obliques. Each of these movements should be performed twenty or thirty times, or until a distinct sense of weariness is produced.

Clinical Report on Heroin.—BEKETTOV (*Wratsch*, No. 19, 1899) has given to twenty-five patients the product of morphin and acetic acid, called heroin. The dose used was $\frac{1}{12\frac{1}{5}}$-grain, in the form of a powder. He found that it lessened cough, so that patients were able to sleep, who before had been kept awake by constant coughing. If there was an increased respiration from cough or painful pleurisy, under the influence of heroin the respirations became slower and deeper. If, however, dyspnea was due to some cardiac condition, or to diminished pulmonary surface, as when cavities were present, it was not affected by the heroin. The drug had no effect on the circulatory or digestive systems. It produced sleep if the cause of insomnia was pulmonary. In wakefulness due to nervous conditions it was not so satisfactory. In hemoptysis it seemed the ideal remedy, preventing cough which is so disastrous under such circumstances. Some patients became accustomed to the drug, so that the dose had to be increased slightly; in others the same dose produced the same therapeutic effect although the administration was continued for weeks. In no instance was more than $\frac{1}{3}$-grain given during the twenty-four hours, nor a larger single dose than $\frac{1}{60}$-grain.

Chloral in Typhoid Fever.—DUMONT (*Rev. de Therap. Medico-Chir.*, May 15, 1899) describes the effect of the administration of chloral, sometimes associated with morphin for persistent insomnia occurring in typhoid fever. This method of treatment has been carried out in Lancereaux' wards with good results. Not only did sleep follow, but restlessness, delirium, and nervous exhaustion were thereby prevented. As a natural consequence, the general condition of the patient was improved, and the duration of the fever, as well as that of convalescence was materially shortened.

Resection of the Sympathetic for Epilepsy.—AMAT (*Bull. Gen. de Ther.*, May 15, 1899) reviews the records of the cases of epilepsy which have been treated by resection of the cervical sympathetic, and shows that this operation is most unsatisfactory. While some apparent cures have been reported, in other instances the operation has resulted in an immediate increase in the number of epileptic seizures, and in some patients trophic disturbances have manifested themselves at a considerable time afterward. Hence the wise physician will keep to his treatment by bromid, which if it rarely cures, often benefits to a considerable degree, and never does serious injury.

Treatment of Hematuria in Malaria. — WHITEHALL (*New Orleans Med. and Surg. Jour.*, June, 1899) dis-

putes the idea that quinin is not a good remedy in the treatment of hematuria occurring in malaria. He cites three cases in which he treated patients suffering from a severe form of malarial hematuria with large doses of quinin (60 to 80 grains in twelve hours) with prompt recovery. There was no doubt that the hematuria in these cases was of malarial origin, and as the quinin was not given until after the blood appeared, it could not have been caused by the medicine, as has sometimes been claimed.

New Method of Closing the Peritoneal Cavity.—O'Hara (*Brit. Med. Jour.*, June 10, 1899) treats the peritoneal opening in the following manner: The incision through the peritoneum is never made more than four or five inches in length. If additional room is required the opening is stretched. As the membrane is very elastic it readily lends itself to this procedure. When the operation is over, a purse-string suture of kangaroo tendon is passed completely around the opening in the peritoneum, beginning at the middle of the incision. When this is drawn up and tied the peritoneal cavity is perfectly closed against leakage from without, and there is no raw surface within to form adhesions to intestinal coils, etc. The suture is easily applied, and the peritoneum is in a far better condition to withstand any post-operative vomiting then after the ordinary suture. The remaining layers of the abdominal wall are closed by interrupted sutures. O'Hara has never seen any bad results follow this method of closure.

Arsenic in Chorea.—As the pathogeny of chorea is very complex, the therapeutic indications are correspondingly variable. Féré ("Twentieth Century Practice", vol. x.). There is as yet no specific treatment. Among the factors entering into the production of chorea we must consider a nervous temperament, infection, shock, general debility, disturbed sleep, etc. When the chorea is associated with debility marked by anemia, general treatment is the best antispasmodic. Here arsenic has had and still enjoys a well-merited reputation, especially for chlorotic and lymphatic patients. It should be given in large doses, such doses being less dangerous than small ones, long continued. Arsenious acid, gr. $\frac{1}{30}$, increased by gr. $\frac{1}{30}$ daily for children from eight to ten may be given, or Fowler's solution, from 5 to 8 drops a day for children and from 10 to 20 drops a day for adults, and gradually increased. Toleration will be facilitated by diluting the solution with a tumblerful of either alkaline or acid carbonated water, which may be taken in two or three portions during the hour following meals, or if Fowler's solution is very badly borne by the stomach it may be administered hypodermically in cherry-laurel water (to diminish the pain of the injection). The amount of the first injection should be $\frac{1}{50}$ c.cm. ($\frac{1}{3}$ m.), and this is increased by an equal quantity every day. Or arseniate of sodium may be used in rapidly increasing doses, gr. $\frac{1}{30}$, $\frac{1}{10}$, $\frac{1}{10}$ daily for slight cases in children. In severe cases one may begin with gr. $\frac{1}{12}$ daily and increase the quantity by $\frac{1}{12}$ gr. every day until gr. ss. is reached. After continuing its maximum for three days the quantity is again diminished by $\frac{1}{12}$ gr. each day. Should treatment by the use of arsenic fail after twenty days it should be discontinued; otherwise it may be kept up several days after the cessation of the movements. One must guard against arsenic poisoning. With this drug iron, cinchona, cod-liver oil, phosphate of lime, etc., may also be employed. Féré has not used antispasmodics (bromids, etc.) extensively in chorea, for the reason that he prefers to treat the general condition rather than the spasms.

Treatment of Incontinence of Urine in Children.—(Thomson, "Clinical Examination and Treatment of Children.") Much more benefit can be gained from the use of sedatives than either stimulating or tonic remedies. Of course, any physical cause, as phimosis, should be removed, and the child should not be allowed to drink anything after five or six o'clock in the afternoon. He should be awakened at eleven or twelve o'clock, and made to empty his bladder. Scolding or punishing the child is of no avail, and should not be done. Belladonna is the most valuable remedy, and should be given in large doses, so that the pupils should be moderately dilated and the throat be somewhat dry at bedtime. Twenty or 30 drops of the tincture may be given to a child four or five years of age at bedtime, and to an older child, from six to ten years of age, 30 drops may be given in the afternoon, and the dose repeated at night. If necessary this dose may be gradually increased up to a dram. If this should fail to prevent the wetting of the bed, the fluid extract of ergot, 20 drops three times a day, often gives good results. Tincture of nux vomica often is efficacious, especially when used in connection with belladonna.

Treatment of Simple Conjunctivitis.—Ohlemann ("Ocular Therapeutics") in acute cases advises the use of cold compresses and the following lotion:

℞	Zinci sulphat.	gr. $\frac{2}{5}$
	Aquæ dest.	ʒ iv.

Or

℞	Plumbi acetat. neutralis.	gr. $\frac{1}{5}$
	Aquæ dest.	ʒ iiss.

In chronic cases, in which the epithelium of the cornea is intact, 6 to 10 drops of a 15-per-cent. solution of lead-water in a wineglassful of boiled water should be applied on compresses to the eye two or three times a day for fifteen minutes at a time. The following ointment is very efficacious:

℞	Hydrargyri oxidi flav.	gr. iii
	Vaselini.	ʒ iiss.

When additional redness of the edges of the lids is present washes are sometimes not well borne. In such cases the following ointment should be used at night:

℞	Hydrargyri precip. alb.	gr. iii–ivss
	Zinci oxidi alb.	gr. ivss–viiss
	Aceti plumbi	gtt. iv–vi
	Vaselini	ʒ vi.

In chronic cases of an eczematous nature this ointment is useful:

℞	Ichthyol.	gr. $\frac{3}{10}$–$\frac{7}{10}$
	Amylis, Zinc. oxidi aa	ʒ iiss
	Vaselini	ʒ vi–gr. xxv.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, JULY 29, 1899.

PUERPERAL FEVER; ITS BACTERIAL CAUSE AND SERUM-THERAPY.

THE deaths which appeal most to the physician are undoubtedly those which occur in child-bed. Despite our increased knowledge concerning the germ origin of the diseases which prove fatal during the puerperium we have not been able to entirely prevent the occurrence of puerperal fever. It had been hoped that streptococcic serum would prove of great service in the treatment of the disease, and in a certain number of instances it appears to have been efficacious, but on the whole its employment has been a source of keen disappointment.

It has been assumed in thus trying streptococcic serum as a specific remedy, first, that puerperal fever is always due to a streptococcus infection, and secondly, that all micro-organisms that grow in chains and take the ordinary anilin stains belong to the same species. Neither of these assumptions is justified by the facts. Puerperal fever undoubtedly is sometimes due to other germs than to streptococci, and it is extremely probable that the diphtheria bacillus sometimes plays a rôle in the etiology of the disease. At times there is perhaps a mixed infection by these germs, as in the throat, and unless care is taken in culture methods it might seem as though only the streptococcus were at work. In infections of the bladder the bacillus coli communis is so often the causative agent that one is tempted to wonder if it plays a rôle in uterine infections also. Adhesions between the uterus or adnexa and intestines often exist as a result of former inflammatory conditions, and by means of these the wandering of intestinal bacteria like the bacillus coli is favored during the post-partum period, when extensive lymphatic absorption occurs. In addition, at this time the uterine tissues are being dissolved in the body juices, and so furnish excellent culture material for the multiplication of micro-organisms. These facts would explain at the same time the origin of certain cases of so called idiopathic infection. The demonstration of the bacillus coli in the process would be extremely important since recent work in France and Italy has shown that the manufacture of a serum which is protective against its infection is possible.

As to unity of species of all streptococci, that is largely an exploded idea. The hope of securing a specific serum depends on our finding some method of surely distinguishing the various forms of microbes that grow in chains. The prospect of successful serum-therapy of puerperal fever, then, depends on a more exact knowledge of the etiology of the disease. In order to bring this about a large number of careful observations will be necessary. The aim is well worthy of the humanitarian sacrifice of time and labor on the part of every one interested in the reduction of mortality among the mothers of the land.

COMPENSATORY THERAPEUTICS.

IT has been found in recent years that by judicious training the impaired functions of many organs may be sufficiently restored to enable them to accomplish for the individual organism practically all that is necessary. Graduated exercises, moderately and nicely adjusted hill-climbing, baths supplemented by judiciously resisted movements while in them, constitute a very helpful resource in the disturbed compensation of chronic heart trouble. Heart lesions do not disappear, and fatty and other degenerative conditions of the heart muscle remain, but a

lasting tone is often imparted to the muscular substance of the heart and the arteries which enables them to do their work with much less difficulty and embarrassment than before.

But cardiac therapeutics is not the only one to benefit by compensatory therapy. Urbantschitzch of Vienna has shown that by aural exercises many supposedly deaf children can be made to hear. He has demonstrated in a number of cases that the hearing faculty is seemingly only lying dormant for want of specific exercise. This exercise it has never secured because the sense of hearing in such people requires much more excitation than in the normal individual. If a special effort is made, however, it responds, and after patient training is able to catch many sounds that before escaped it entirely. The psychical element in hearing is trained to catch the faint inklings of sound that come wandering up through the defective hearing apparatus and that were previously neglected because of their indefiniteness or absolute unmeaningness. This system of developing the faculty of hearing has been found to be effective also in certain cases of deafness due to disease, in which there is no gross lesion of the hearing apparatus.

In tabes, Frenkel's system of exercises enables the physician to relieve to a great extent that most troublesome symptom of the disease, incoordination. To many ataxic patients who have been bedridden for years, walking on the streets, which for them had become either impossible or a torture because of their lack of confidence in themselves, becomes under this treatment not only easy of accomplishment, but a positive source of pleasure. Here, as in the case of the hearing exercises, the psychic element—the training of the attention—is an important part of the treatment, though it seems undoubtedly true, also, that the impaired nerve paths learn by practice to carry more nervous impulses, and do it more definitely than before. That exercise not overdone leads to increase of function, is a maxim that is of wide application in physiological processes, and that it holds good in the case of tabes seems not surprising.

Similar beneficial results have been accomplished here in America in ocular therapeutics by corresponding methods. Patients who suffer from slight errors of refraction have been taught by judicious exercise of their accommodation to compensate for the refractive error, and after a time symptoms disappear even without the use of glasses.

In pulmonary therapeutics exercises have always occupied a notable place, though it is true that of late years even more attention than formerly has been paid to them.

It is evident, then, that we have in this principle of compensatory therapy a very valuable therapeutic measure, and one that deserves even more attention than has been given it. It is strictly in line with the most rational treatment of disease, since its only object is to aid nature, and that by the readiest and most direct means, *viz.*, by guiding and increasing the functional efforts of the organism. Wherever psychic or muscular elements enter into a patient's pathological condition, training is capable of yielding excellent results. In hysterical and nervous affections it has been successfully applied in such methods as the rest cure. In purely mental disease training of the emotions can be most effective for the suppression of symptoms. In such associated psychical states as vertigo, the actual training given to dancers and acrobats may prove of service. In ailments that involve even unstriped muscular fibers, the modern therapeutics of gastric insufficiency and atonic constipation, massage, and electrization is accomplishing much by stimulant exercise.

ECHOES AND NEWS.

Calmette's Serum Effective.—The London *Times* of July 21st contains a report from Allahabad of a well-authenticated cure, by the injection of Calmette's serum, of a snake-bitten patient who was in a state of collapse.

Yellow Fever Decreasing in Mexico.—The Texas State Health Department received official advices from Mexico on July 21st that the yellow-fever epidemic in coast cities and towns is rapidly decreasing in severity. Quarantine has been enforced along the Mexican coast.

More Nurses for the Philippines.—Nine more trained nurses left New York City for the Philippines on July 20th under the auspices of Red Cross Auxiliary No. 3 for the Maintenance of Trained Nurses. When they arrive at Manila they will report to Miss Henshall, who will then have under her direction a corps of twenty-seven nurses.

The Plague at Europe's Doors.—The Paris correspondent of the *Courrier des Etats Unis* states that the plague has appeared in Alexandria, which city is the key of Egyptian commerce. He dreads, therefore, that if quarantine

and medical inspection are not instituted and vigorously enforced, Europe, through the principal Mediterranean ports, will become contaminated.

Santiago's Epidemic Is Ended.—Nothwithstanding the fever epidemic, only sixteen deaths were reported at Santiago during the week ending July 19th. This is the lowest mortality the city has ever known. No new cases were reported after July 14th, and nearly all the patients in the hospitals are convalescent. General Wood will not lift quarantine, however, until all danger is past.

A Universal Language for Men of Science.—At a recent meeting of the Prussian Academy of Sciences, Professor Dills spoke of the need of a universal language for men of science. He considers Volapük an artificial product of little use. English is his choice as the world-language because of its wide prevalence and because its simple structure and grammar make it eminently suitable for such use.

Assistant Surgeon of the First California.—Dr. George H. Richardson of the class of '91, Medical Department of the University of Pennsylvania, who was sent to the Philippines on May 17, 1898, as acting assistant surgeon, has been appointed captain and assistant surgeon in the First California United States Volunteer Infantry. Dr. Richardson's experience has been a very varied one, he having arrived from Burmah only a few months before sailing for Manila.

A Physician Assaulted.—Dr. Robert P. Froehlich of 61 East 105th street, New York, was assaulted and kicked into insensibility on July 24th, by a gang of roughs because he had dressed the wound of a non-union motorman belonging to the Second avenue street-car line whom they had maltreated. Though painfully injured, no bones were broken, and the physician hopes to be able to leave his house within a few days. Steps have been taken to apprehend his assailants.

Asylum for Insane Indians—The asylum for insane Indians at Canton, S. D., for which Congress made an appropriation of $42,000, with an additional $3000 for the purchase of ground, will soon be erected. Out of a total of 250,000 Indians in the United States there are only 58 who are insane, 1 doubtful, 6 idiotic and 2 partly idiotic. It would seem, then, that the simple physiological life of the barbarian has some advantage over the brain-paralyzing existence characteristic of civilization.

Willard Hospital Inspected.—Among 2000 inmates of the Willard State Hospital thirty-four cases of diphtheria have been found. On July 21st the New York State Board of Health ordered a rigid quarantine of that institution. The diphtheria has been of a mild type and no deaths have been reported. All the diphtheria patients are being treated with antitoxin, and immunization doses of the serum have been administered to many of the other inmates. Dr. Macy and his assistants are attacking the disease systematically and effectively.

Post for Army Consumptives.—Secretary Alger has approved Surgeon-General Sternberg's recommendation that Fort Bayard, N. M., be set aside for the treatment of army consumptives. General Sternberg will immediately prepare to equip the post, from which some of the troops will be withdrawn to make room for patients. A competent corps of surgeons will be assigned to duty there, but no special medicinal system will be followed, great reliance being placed on the benefits of the climate. It is proposed to transfer several patients to the new sanatorium from the Soldier's Home near Washington.

The Tobacco-smoking Evil.—A writer in the German scientific periodical *Prometheus* declares that over-indulgence in tobacco will prove the ruin of South-American peoples. Not only do children of two or three years smoke all day long, but mothers have been seen trying to quiet their babies by putting cigars in their mouths. At the recent annual conference of the Lancashire and Cheshire branch of the British Medical Association Dr. J. Hilton Thompson propounded a new theory in respect to cigarette smoking. He showed the distinct presence of carbonic-oxid gas in tobacco smoke, and when inhaled from cigarettes, he said, it has the same injurious effect on the system as choke damp in collieries.

A Prize for a Thesis on Army Rations.—Appreciative of the necessity for proper food for the men of the army and navy serving in tropical climates, Dr. Louis L. Seaman of New York City, late Major-Surgeon of the First Regiment, United States Volunteer Engineers, has offered through the Military Service Institute of the United States the sum of $100 in gold—or a medal of equal value as the successful competitor may elect—for the best thesis on "The Ideal Ration for the Army in the Tropics." This competition is open to commissioned medical and other officers of the army and navy, volunteer and regular. All papers should be submitted before March 1, 1900. The Board of award will be Colonel Weston, Acting Commissary General; Lieutenant-Colonel Charles Smart, Deputy Surgeon-General, and Lieutenant-Colonel William E. Dougherty, Seventh United States Infantry. The headquarters of the Military Institute is at Governor's Island, New York Harbor.

Queen Victoria's Family.—The Queen's family is now an exceedingly large one, how large can perhaps best be realized when the number of her direct descendants is set forth in tabular form:

Queen	1
Sons and daughters living	7
Grandchildren	33
Great-grandchildren	31
Total	72

Besides these direct descendants, the Queen has something like 160 cousins and descendants of cousins. If they are counted with the Queen's own children, grandchildren, and great-grandchildren, the members of the royal family are increased to not less than 230. The ages of the four generations of the royal family in the direct line of succession are:

Queen	80
Prince of Wales	55
Duke of York	34
Prince Edward of York	5

—*London News.*

The "Kissing Bug."—"This and other papers are recording daily the sufferings of people who think that they have been bitten by a newly invented insect. That the bites are inflicted by something is probably true, and there is no doubt at all about the tumefaction and the pain which the doctors are called upon to reduce and assuage, and yet there is not the faintest evidence to show either that a strange insect has made its appearance in the country or even that some familiar one has become more fierce and venomous than usual. The entomologists unite in denying the existence of a 'kissing bug,' and though little creatures by the dozen of one sort or another have been submitted to these authorities as criminals caught in the very act of osculatory attack, still the learned ones refuse to be convinced, and not only give the accused names as ancient as they are long, but assert and, if need be, prove that the incriminated bugs couldn't bite if they would, and wouldn't if they could. The whole trouble seems to be the effect of misguided and overexerted imaginations. Charlatans of the species that has received general mention once or twice in this column claim that all, and occasionally demonstrate, that a few bodily ills can be cured by 'faith.' This 'kissing bug' epidemic tends to show that 'faith' can cause functional disturbances as well as remove them. But everybody knew that before."—*New York Times.*

Railway Accidents in the United States.—The Interstate Commerce Commission makes the following report for the year ending June 30, 1898: The total number of casualties to persons on account of railway accidents during the year ending June 30, 1898, was 47,741. The aggregate number of persons killed as a result of railway accidents during the year was 6859, and the number injured was 40,882. Of railway employees, 1958 were killed and 31,761 were injured during the year covered by this report. With respect to the three general classes of employees, these casualties were divided as follows: Trainmen, 1141 killed, 15,645 injured; switchmen, flagmen, and watchmen, 242 killed, 2677 injured; other employees, 575 killed, 13,439 injured. The casualties to employees resulting from coupling and uncoupling cars were, persons killed, 279; injured, 6988. The corresponding figures for the preceding year were, killed, 214; injured, 6283.

The number of passengers killed during the year was 221 and the number injured 2945. Corresponding figures for the previous year were 222 killed and 2795 injured. In consequence of collisions and derailments 72 passengers were killed and 1134 passengers were injured during the year embraced by this report. The total number of persons, other than employees and passengers, killed, was 4680; injured 6176. These figures include casualties to persons classed as trespassers, of whom 4063 were killed and 4749 were injured. The summaries containing the ratio of casualties show that 1 out of every 447 employees was killed and 1 out of every 28 employees was injured. With reference to trainmen—including in the term enginemen, firemen, conductors, and other trainmen—it is shown that 1 was killed for every 150 employed and 1 was injured for every 11 employed. One passenger was killed for every 2,267,270 carried and 1 injured for every 170,141 carried. Ratios based on the number of miles traveled, however, show that 60,542,670 passenger-miles were accomplished for each passenger killed and 4,543,270 passenger-miles accomplished for each passenger injured.

MEDICAL MATTERS IN NEW YORK.

A NEW CURE FOR INSOMNIA—MATCHES IN TEA, A NEW DELICACY FOR CONVALESCENTS—BELLEVUE'S ACROMEGALY PATIENT DEAD—MORE TETANUS—THE ACTIVE CHRISTIAN-SCIENCE "HEALERS"—THE BABIES' HOSPITAL SUMMER BRANCH—THE HEALTH DEPARTMENT AND ITS NEW QUARTERS—YELLOW-FEVER PATIENTS DISCHARGED.

WE have heard of the man who carried a hot brick in his pocket to keep his feet warm, but never until now of one who attempted to woo the goddess of sleep by inhaling illuminating-gas. A painter, forty-two years of age, residing in Ludlow street, is the latest aspirant for fame in this particular line, and that the sleep induced by this method of treatment did not continue for all time was due only to the opportune discovery of his condition by a police officer. To the magistrate before whom he was haled the painter explained that he had found this original recipe for insomnia in a newspaper, and had determined to give it a trial.

Bellevue Hospital must have its periodical sensation. This time it is due to the accidental introduction into one of the male convalescent wards of a new beverage, the popularity of which, however, appreciably waned after the first draught. It all happened in this wise: A few days since an attendant brought a vessel containing a gallon of hot tea from the hospital kitchen and placed it on a table in the ward preparatory to its distribution to the patients. While his attention was momentarily distracted, one of the patients, in reaching for a glass on the table, overturned a box of matches into the tea. Another attendant started in to distribute the nectar, but noticing the matches floating about in it, decided that a combined wood-pile and weak-tea diet might not be exactly the fuel the convalescents most needed, and so fished them out, but on general principles being opposed to unnecessary waste and all unconscious of the fact that the phosphorus had been dissolved off the matches, proceeded to ladle out the tea. It was not long before there was a sound not exactly of revelry by night, and liberal use of emetics and of stomach-tubes was necessary before the ward was restored to its accustomed matchless equanimity. Fortunately no lasting ill effects resulted from the radical departure from old-time methods, and in future the tea will be served in the regulation way, without frills or addenda.

Then, too, Bellevue has lost its star patient, and great is the regret thereat. Mary Fogarty, fifty-one years of age, who was affectionately and widely known to her friends and neighbors in West Sixtieth street as "Big Nose Mary," died on the afternoon of July 21st from acromegaly. Common report has it that she was the first patient ever received at the hospital suffering from this disease,

although this statement has not been officially confirmed. She weighed nearly three hundred pounds at the time of her death, was nearly, if not quite six feet in height, and wore a heavy beard and mustache. Her hands, feet, and nose especially showed the advanced stage of the disease with which she was afflicted, all being enlarged to enormous proportions.

Tetanus antitoxin has again been tried and found wanting, which, perhaps, is not surprising as it has met this fate so often in this vicinity during the past two weeks. Guiseppi Consumanno, fourteen years old, while patriotically celebrating the Independence anniversary of the land of his adoption, ploughed a furrow on one of his hands with the assistance of a pistol and a small-caliber bullet. Ten days later symptoms of tetanus developed, and on July 16th the boy was admitted to the Columbus Hospital. Antitoxic serum was injected, and every effort made to save his life, but he died on July 22d. This is the twenty-first death from tetanus that has occurred in and about the city since the Fourth of July, and all can be traced directly to wounds inflicted by firearms or fireworks on that day.

The medical and lay press devote columns to ridiculing the claims of Christian-Science "healers," and yet this sect goes merrily on its way contributing to the mortality records. A certain Mr. Robertson, seventy-eight years old, formerly a well-known artist, was the latest victim in this city. His ailment was said to be gastro-enteritis, and he was ill but twenty-four hours. His daughter, a "first reader," or it may be "primer," in the First Christian Science Church of Orange, N. J., believing prayer to be more efficacious than bismuth under such circumstances, administered the former in large doses, with the result that after the lapse of the number of hours above mentioned no further treatment was necessary. Funeral services were held on the 25th inst.

The managers of the Babies' Hospital at Fifty-fifth street and Lexington avenue, on July 22d opened a new hospital building at its summer branch settlement at Oceanic, N. J. It contains an entirely new feature—two private wards in which sick babies from the hotels and cottages of the surrounding summer resorts can be treated. Heretofore the hospital has accepted free patients only, mostly from New York's tenement-houses, but the managers have been so besieged for private treatment by summer frequenters of the resorts nearby, that they have decided upon this departure. Only children under three years of age are accepted in the free wards, but none suffering from contagious disease. Their stay at Oceanic is not limited, but all are cared for while they need sea air and country living.

The ordinance recently offered at a meeting of the Board of Aldermen to forbid the sale of cigarettes to boys under eighteen years of age has been reported favorably by the Law Committee, to which it was referred, and will be acted upon at the next meeting.

Between 350 and 400 tons of records are now being moved from the present quarters of the Board of Health in the Criminal Court building in Centre street to its new home in the building at Sixth avenue and Fifty-fifth street, which was formerly occupied by the New York Athletic Club. The Health Board was organized in 1865, just after a cholera panic, and was first located in the Police building at Mulberry and Mott streets. Five years ago it moved into the quarters it is now leaving, where it has always had an uncomfortable existence because of the prejudice of the other departments of the city to its presence among them. It will now enjoy a sort of "splendid isolation" in a part of the city where it will be more accessible to the medical profession. Almost every year some new duty is added by the Legislature to its work, and backed up as it is by law and by police of its own, it is a very powerful safeguard of the public health. Its Bureau of Vital Statistics records each year the deaths of 50,000 people and the births of as many others. In the Sanitary Bureau there are five divisions—of general and sanitary inspection, of contagious diseases, of medical sanitary inspection, of inspection of foods, offensive trades and mercantile establishments, and of school inspection; and there is a pathological and bacteriological division. The staff of officers consists of the president, three commissioners, the secretary, counsel, seventeen honorary consulting officers, and twelve salaried executive officers. There are nearly 800 employees in the main office, and the 4 branch borough offices, including 96 sanitary policemen. Its expenses are between eleven and twelve hundred thousand dollars a year and it has an income of about $3000 from the sale of vaccines and antitoxins and from transcripts of records.

Miss L. C. Clendenin, who has been ill with yellow fever and quarantined on Hoffman's Island since her arrival here on the transport "McClellan" from Santiago on July 6th, has entirely recovered and been discharged. Mr. Oscar L. Lackey of Baltimore, the other patient from the transport, who was inoculated with antitoxin serum under the supervision of Health Officer Doty, has also recovered and left for his home.

MEDICAL MATTERS IN CHICAGO.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION—INCORPORATION OF THE ILLINOIS SOCIETY FOR THE PREVENTION OF CONSUMPTION—VOLUNTEER PHYSICIANS AS MEDICAL INSPECTORS—RESOLUTIONS ADOPTED BY THE STATE BOARD OF HEALTH—BEQUESTS OF DR. ROBERT L. REA.

ACCORDING to a preliminary announcement the twenty-fifth annual meeting of the Mississippi Valley Medical Association will be held in this city October 3, 4, 5, and 6, 1899. This is the first time the Association has held its meeting in Chicago, and the local profession, under the leadership of Dr. Harold M. Moyer as Chairman of the Committee of Arrangements, has provided many attractions for the visiting doctors. Among them may be mentioned an attractive program in both medical and surgical sections, and special clinics in all the departments of medicine and surgery, to be given at the various hospitals and colleges before and after the meeting.

The occurrence of the autumn festival at this time is an added attraction. The President of the United States

and his Cabinet, Admiral Dewey, the Premier of Canada, and President Diaz of Mexico have signified their intention of being present. The railroads have promised a one-fare round-trip rate, with a liberal limit to tickets. The Committee of Arrangements will issue a souvenir program which will also be the official program, to the number of 35,000, to be sent to every doctor in the Mississippi Valley and territory contributory to Chicago. In addition to the program of the meeting this will contain a schedule of clinics and a sketch of medical Chicago. Dr. Duncan Eve of Nashville, Tenn., is president, and Dr. Henry E. Tuley of Louisville, Ky., secretary of the Association.

The Illinois Society for the Prevention of Consumption has been incorporated by Drs. Frank W. Reilly, Henry B. Favill, and Mr. Joseph Hughes.

Our City Health Commissioner, Dr. Arthur R. Reynolds, has issued a call for volunteer physicians to serve as medical inspectors, and more than forty have been enrolled upon the books of the department to undertake the house to-house canvas for the purpose of disseminating knowledge as to the care of infants and to inspect sanitary conditions. It is intended by the department that the work shall not be interpreted as being of a charitable nature; the physicians are not required to prescribe or perform medical service except in cases of emergency. In the first place, the object is to instruct mothers and those in charge of infants and children during the hot weather as regards hygiene of the young, their feeding, clothing, bathing, and care, with a view to the prevention rather than the cure of disease. Secondly, the object is the correction of sanitary defects and the abatement of nuisances prejudicial to the health of adults and children alike. The work of the Health Department in a city like Chicago is necessarily vast in its possibilities, and especially inviting to medical students who may wish to become experts in bacteriologic or other research. For this reason the plan of Commissioner Reynolds to increase his office force without expense to the city by admitting recent graduates of medical colleges to the Department Laboratory is to be commended. Of course facilities can be furnished for only a limited number, but this is an advantage, as it gives wide opportunity of selection. It is stated that 2623 bacteriologic examinations were made last year, and 2635 examinations of water, ice, milk, vaccine, lymph, butter, etc., and 30,000 other examinations of ice cream, cheese, and the like. In making tests of this kind medical students with a little training will be able to do efficient work and thus add greatly to the value of the department, while at the same time securing excellent drill in the important province of preventive medicine.

At the July quarterly meeting of the State Board of Health, held in this city, the following resolutions were adopted by the Board:

WHEREAS, Section 2, of an Act to Regulate the Practice of Medicine in the State of Illinois, and to repeal an Act named therein, approved April 24, 1899, in force July 1, 1899, gives the State Board of Health discretionary power as to granting certificates to graduates of legally chartered medical colleges in Illinois in good standing as may be determined by the Board, and,

WHEREAS, It is evident, notwithstanding the discretionary power given the Board, that the true intent and purpose of this Act is to require all persons to prove their qualifications to the State Board of Health by passing an examination; therefore, be it

Resolved, That all applicants for a State certificate to practise medicine and surgery in the State of Illinois, who are graduates of medical colleges in good standing, as may be determined by this Board, shall, before receiving a certificate, be obliged to pass an examination such as contemplated in Section 2, of an Act to Regulate the Practice of Medicine in the State of Illinois, in force July 1, 1899.

Resolved, That the phrase "medical college or institution in good standing," in the first paragraph of Section 2, of the Act to Regulate the Practice of Medicine in the State of Illinois, in force July 1, 1899, is hereby defined to include only legally organized, properly conducted medical institutions, having a sufficient and competent corps of instructors and ample facilities for teaching, dissections and ambulatory and hospital clinics, which conform to the requirements relative to the preliminary education of matriculants, the course and period of study, the number, character, and length of lecture terms, the duration of attendance on hospital and clinical instruction, which obtain in the majority of medical colleges in the United States.

The Illinois State Board of Health, however, will not consider in good standing after January 1, 1900, any medical institution which does not require of all students (excepting graduates of reputable colleges of arts and sciences, or reputable colleges of dentistry, pharmacy, or veterinary medicine, to whom one year's advanced standing may be granted), as a condition of graduation, an attendance of four full courses of lectures of at least six months each, in four separate years, no two courses commencing or ending in the same calendar year of time.

Resolved, That no medical college issuing a catalogue of announcement in which are contained misrepresentations respecting its teaching, clinical or hospital facilities, its faculty, or its courses of study, or false representation as to the number of students matriculated or in attendance, will be regarded as in good standing.

Dr. Robert L. Rea, who died July 10th, bequeathed to the Northwestern University at Evanston $10,000 with which to endow the Department of Anatomy, which shall be known as "The Rea Professorship of Anatomy." The College of Physicians and Surgeons, of which the deceased was a faculty member nearly twenty years, receives $5000, to be devoted to the educational expenses of worthy and indigent students. The bequests to the Northwestern University and to the College of Physicians and Surgeons are direct and made payable inside of three years after the death of Dr. Rea.

For Leucorrhea.—DALCHE claims good effects from the use of tampons soaked in a mixture of lactic acid, 3 parts, and glycerin, 100 parts, which he first tried in the belief that lactic acid is the natural agent for vaginal antisepsis.

CORRESPONDENCE.

OUR LONDON LETTER.

[From Our Special Correspondent.]

POISON BY POST AND THE INSANITY PLEA—CANCER DELEGATE TO AMERICA—ANOTHER CAUSE OF CANCER—CLIFFORD ALLBUTT'S POLYCLINIC LECTURE—SIR WILLIAM HENRY FLOWER—UNIVERSITY EXTENSION WORK IN MEDICINE—THE MEDICAL DEFENSE UNION.

LONDON, July 16, 1899.

ENGLISH justice has a grim way of "arriving" with surprising promptness. The girl, Mary Ansell, whose callous cruelty in poisoning her imbecile sister for the sake of her insurance money, by means of a cake sent by mail, containing phosphorus paste, we referred to some three months ago, was put on trial last week. She was found guilty and condemned to death inside of forty-eight hours, and was duly hung to-day. A petition was presented to the Home Secretary, urging that several of her family were mentally defective and that the girl herself was probably insane, but as it was overwhelmingly proved at the trial that the prisoner had deliberately taken out an insurance policy on her sister's life without her knowledge, then tried twice to poison her, once unsuccessfully by means of a package of tea, and that she wanted the money in order to enable her to get married, as her fiancé and even she herself admitted; a lunatic capable of that degree of ingenuity and calculation would be a criminal monster, which any community would be justified in hanging in self-defence, and the petition was therefore refused.

Exit consumption, enter cancer. The Cancer Society of London has despatched an envoy, Dr. Arthur Duffy, to the United States to study the American methods of investigating the disease, and especially those of the New York State Cancer Laboratory at Buffalo, under the direction of Dr. Roswell Park. The society's chairman, Sir Charles Cameron, M.P., has announced his intention of moving in Parliament for the appointment of a royal commission to investigate the alleged alarming increase and for the collection of information bearing upon the causation and methods of prevention of the disease.

Dr. Lambert Lack's announcement that he has discovered the cause of cancer in certain disturbances of the basement membrane of epithelium, by imitating which in the lower animals he has succeeded in producing cancerous growths, is read with considerable scepticism. It recalls too vividly the old "isolation" or "strangulation" theory of Cornil, according to which under-proliferation of the connective tissue was the starting point, by cutting off buds or islands of epithelium which once isolated set up reproduction on their own account. However, all will await the publication of the theory and its details in the regular journals with interest. No further details have yet been received from "Dr. Bra of Paris" since his preliminary announcement of the discovery of the "cancer germ" in the daily papers a couple of months ago.

Professor Clifford Allbutt of Cambridge lectured last week before the members of the London Polyclinic on "Cerebral Syphilis." This was the first of a series of single lectures or short courses of lectures by distinguished members of the profession, both of London and the Provinces. The work at the Polyclinic will probably be suspended during the month of August, at the close of the present (second) term of lectures and demonstrations.

The death of Sir William Flower, the distinguished zoologist, has brought to mind the well-nigh forgotten fact that he was originally an active member of our profession. He was a regimental surgeon all through the Crimean War and anatomist and assistant-surgeon at Middlesex Hospital for several years after that. Then for twenty-three years he was Curator of the Museum of the College of Surgeons and for five years Hunterian Professor of Comparative Anatomy in the College, so that although he early retired from actual practice he was intimately connected with the science and teaching of medicine during the greater part of his career. Flower was no giant or discoverer, although he belonged to a generation of such, but he has left behind him a mass of excellent and most valuable work. He was one of the greatest museum-arrangers, administrators, and in the best sense "popularizers" that England has known. The sacred traditions of the Hunterian Museum hardly gave him a fair opportunity, although he did much for the collection and toward its rationalization, but the Natural History Department of the British Museum, South Kensington, became in his hands, one of the model museums of the world, not merely a superb collection, but one great illustrated manual of zoology, the pages of which even he who runs may read. No American physician visiting London can afford to miss spending a day in this splendid monument of the genius and organizing skill of one of our colleagues.

An interesting experiment of medical university extension work has just been tried with great success in Chester. The medical men of that city and the adjacent towns formed a class and invited Dr. Sheridan Delepine, Professor of Pathology in Owens College, Manchester, to deliver a course of lectures on bacteriology. These have been well attended and greatly enjoyed, and the plan is to be extended to other subjects and in other districts.

The Medical Defense Union is coining golden opinions in the profession by its efficiency and vigor in defending suits for malpractice brought against its members. Dr. Woodley Stocker writes to the *Lancet* to express his appreciation of the inestimable value of its assistance in winning a suit of this description brought against him in connection with an injured hand. The value of legal counsel with training and experience in this class of cases, the relief from the most crippling part of the expense, and above all the feeling that you have at your back an organization representing the entire profession are worth everything to the victim of one of these suits. Usually he feels that he has the sympathy of the profession—but must fight alone and pay all the costs himself, and that, too, in a trial from which the utmost he has to hope is an acquittal, which probably half the community will persist in regarding as a miscarriage of justice.

The London School Board has reappointed Dr. C. E.

Shuttleworth and Dr. May Dickinson Berry for another year to continue their admirable work in examining defective children and advising as to the best methods of their education.

The annual meeting of the Jenner Institute has just been held and much enthusiasm was manifested at the encouraging prospects opened up by Lord Iveagh's superb donation. The work of the past year was reported as satisfactory and the plans for the future outlined. These are far-reaching, and include reseach work in comparative pathology.

TREATMENT OF TETANUS BY OPIUM.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Mr. J. F. and grandson were unloading wheat one afternoon at 5 o'clock. The old gentleman reached for a sheaf, and at the same moment his grandson who was looking the other way, ran the tine of a pitchfork into the back of the middle finger of his right hand near the metacarpophalangeal articulation. The wound caused great pain, which became agonizing at 8 P.M., at which time I was sent for. I found the patient livid and gasping for breath. The pain had extended up the arm and to the neck, chest, and heart, the jaws being stiff. One dram of pulverized opium was put in a basin, a pint of boiling water poured on it, and the injured hand being held over the basin, the hot liquid was poured on it with a tablespoon. When a half dozen spoonfuls had been applied the patient experienced wonderful relief. I continued the application for perhaps half an hour, reheating the opium solution several times, and during the night several applications were also made, but no further trouble occurred, and the next day the patient was well, with the exception of some soreness about the hand.

Since then a lady came to see me in regard to her foot which had been injured by treading on a rusty nail two days before. She had suffered great pain, and some stiffness of her jaws was present. When the wound was touched a shock seemed to go through her whole body. A pint of the opium solution was prepared, and her foot immersed in it, the solution being as hot as could be borne. In half an hour the patient expressed great relief. She followed this treatment occasionally for several days, and the symptoms entirely disappeared.

I have treated some half dozen cases of injury of the hands and feet in the same way, with perfect relief in each case. I learned the use of the infusion of opium from the late Professor Nathan R. Smith, while a student at the University of Maryland from 1866 to 1869. It was a favorite prescription with him, and has been likewise with me. I had always used it either warm or cold. The extreme illness of Mr. F. made cooling of the liquid impossible, and thus I accidentally became acquainted with the virtues of the hot infusion of opium. Recent reports of fatal cases of tetanus following slight injuries has prompted the writing of this letter, and I hope that other physicians may have equal success with the above treatment. JOHN J. LIGGET, M.D.

LADIESBURG, MD., July 19, 1899.

COMMUNICABLE MALARIAL FEVER — REMOTE PROGNOSIS OF PERICARDITIS—HYDRAMNION IN CASES OF HOMOLOGOUS TISSUES — UNSUCCESSFUL NEURORRHAPHY—A DISCUSSION ON COXA VERA IN ADOLESCENCE.

THE Royal Medical and Chirurgical Society, June 13th, listened to a paper by ROGERS on the eradication of Assam epidemic malarial fever. His view was that this is an intensified form of malarial fever, which after a succession of very unhealthy years, has attained the power of being slowly communicable, usually in an indirect manner, from person to person. The success of his recommendations for the eradication of the disease has confirmed this opinion as to its nature. These recommendations were, briefly, as follows: (1) All newly imported coolies should be placed in fresh lines and not allowed to enter old infected ones; (2) in slightly infected lines all infected persons, together with their households, should be moved out into separate segregation lines and the huts which they have inhabited should be burned and not rebuilt; (3) in badly infected lines all the healthy people should be moved out during the dry cold weather months when infection is at a minimum and placed in new lines, while the infected persons and their households should be segregated and the infected line abandoned.

SEQUEIRA read a paper on the remote prognosis of pericarditis. Recent work seems to show that the pericardium acts as a support to the heart during muscular exertion. If the pericardium is softened and dilated by inflammation this support may be lost, and under severe strain the chambers of the heart may therefore dilate at once. If the pericardium becomes dilated and adherent to the chest wall the effect on the heart of working in a dilated sac may become evident in the direction of lack of compensation. If the pericardium is adherent but not dilated the effect will be small. Clinically the 100 cases which he had examined fell into three groups: (1) those in which there was perfect compensation of the heart; (2) those in which compensation was easily broken; and (3) those in which compensation never occurred. In the first group there were thirty-one cases. All the patients were more than fourteen years of age. The pericardium was undilated: there were no symptoms and practically no physical signs. In the second group there were eighty-six cases. The young patients, and especially young females, formed the bulk. There were all gradations in the severity of the symptoms. Many of the patients were in and out of hospital for years, while in some compensation occurred once only. In the young females (from six to fifteen years old at the time of the acute attack) death occurred on the average in little over two years. In the males, in whom the original attack occurred between the same ages, the average length of life was 3¼ years. The extremes were, of course, very wide of this. In the fatal cases the pericardium was found to be dilated and adherent and the severity of the symptoms depended in a great measure upon the amount of the dilatation. Sequeira had found an interesting re-

lation between the annual increase in the body weight and the age at which death took place in the cases in which the acute attack occurred in early childhood. In the third group of cases, thirteen in number, compensation was never complete. In some this depended upon the fact that the dilatation of the pericardium was progressive. The patients were all young and death resulted in from three to nine months after the acute attack. The effect of concomitant valvular disease and of myocarditis was considered and Sequeira concluded that valvular lesions were of little moment in many cases and that myocardial degeneration could not induce the enormous dilatation of the heart so often observed if the pericardium were undilated. Further, the amount of hypertrophy of the heart in cases of adherent pericardium appeared to be in the main dependent upon the amount of dilatation of the cardiac envelope. Sequeira concluded that he had proved that the amount of dilatation of the pericardium must be taken into account in the consideration of the remote prognosis of acute pericarditis and that influences, such as the increase in the body weight and the amount of muscular exertion, which augment the labor of a heart working in a dilated pericardium, tend to impair the power of compensation.

At the Obstetrical Society, June 17th, WILSON spoke of hydramnion in cases of unioval or homologous twins. Although twins derived from separate ova are nearly seven times more frequent than those derived from a single ovum, hydramnion apparently occurs about as frequently in one class as in the other. The paper was founded on two cases which occurred in his own practice, and on twenty others which he had collected. The history of a case of this kind is that the patient, usually a multipara, at the fourth or fifth month and without any assignable cause undergoes rapid enlargement of the abdomen, which in the course of a few days or weeks leads to extreme distress from the pressure. The affection ends in nearly every case in spontaneous delivery before the end of the seventh month, although in about twenty per cent. labor has to be induced. The contents of the uterus are found to be twin fetuses of the same sex, one of which is decidedly larger that the other, and is enclosed in an amnion containing an enormous excess of fluid. There is a single placenta common to the two fetuses, a single chorion, and two amnia. The heart and kidneys of the larger fetus are hypertrophied, often enormously. Neither fetus shows any malformation and the mother is healthy. The cause of the hydramnion is found in the relation of the vessels of the two fetuses to the common placenta. The twin whose vessels run a shorter or more direct course obtains an undue share of blood from the placenta, in which anastomoses take place between the vessels belonging to the two fetuses. In this way one fetus grows faster than the other and the heart of this one becomes not only absolutely but also relatively larger than that of the other. This leads to an increased secretion from the kidneys, and possibly from the skin and the placenta. The appropriate treatment is the induction of premature labor by puncture of the membranes.

At the British Orthopedic Society, May 27th THOMAS showed a patient in whom the left popliteal nerve had been injured by a kick from a horse, and talipes equinovarus had followed. Neurorrhaphy having failed, tarsectomy was performed with an excellent result.

TUBBY said that it is difficult or impossible to restore a nerve by suture when the division has occurred at or near the point where the nerve breaks up into branches. He further described a case occurring in his own practice in which spastic hemiplegia with flexion of the elbow and wrist and pronation was treated by open section of the flexor tendons, especially the flexor carpi radialis, and detachment of the pronator radii teres from its insertion. A hole was made in the interosseous membrane and the tendon was passed round the back of the radius to its outer border and fixed, thus reversing the action of the muscle. The wrist was kept midway between flexion and extension by means of splints. In six weeks the patient could pick up a pin.

KEETLY opened a discussion on coxa vara. He described types of the two chief varieties which commence in adolescence. The deformity is rachitic in origin. The partial or even total absence of rachitic changes in other parts is no disproof of this, as the older the patient the more localized do rachitic changes tend to be. The various modes of osteotomy which had been carried out or proposed, including a new method, were described. In theory the neck of the bone should be operated on; in practice the trochanteric region is more convenient. Decreased angle of the neck and shaft forms the striking feature at a first glance at the deformity, but the main changes are in the neck itself, especially near the head. In fact, coxa vara is a rachitic deformity of the upper epiphyseal region of the femur. The deforming influence sometimes extends far down the shaft. Compensatory genu valgum is common. The speaker called attention to a peculiar expansion of the facial bones, giving prominence to the eyeballs and width and flatness to the upper half of the face. Coxa vara in cases of early rickets is very common, but cases during adolescence are rare. The commencement of the flood of modern literature on the subject dated from his own paper in the *Illustrated Medical News* of September 29, 1888. The hip-joint is healthy in these cases. For this and for other obvious reasons excision is not justifiable.

LITTLE found great difficulty in accepting the theory that late rickets is the cause. In none of the extremely rickety skeletons in the London museums is anything approaching the deformities depicted by Kocher and others found. It seems to be a process *sui generis*. Charpentie had shown that osteitis may cause the deformity.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held March 15, 1899.

THE President, WILLIAM STEVENS, M.D., in the Chair.

SCURVY ASSOCIATED WITH MEMBRANOUS COLITIS.

DR. J. H. FRUITNIGHT: I have recently had under

observation a case of scurvy occurring in a boy, eight years of age, the child of wealthy parents. He had been allowed to eat a great deal of salt meat and salt smoked fish, these forming his principal diet, for he would not eat potatoes or any other vegetables. The disease showed itself first by pain about the joints, particularly near the knees, ankles, and wrists; ecchymotic spots also appeared in the neighborhood of these joints. The gums soon became spongy and bled easily. Child also complained of great pain over the region of the descending colon which seemed to indicate some intestinal disorder. An enema was given and this brought away a strip of membrane six inches in length, stained with blood, with the result that the abdominal pain ceased. The intestinal trouble lasted about ten days, the temperature reaching 103° and 104° F. My theory is that there was a submucous extravasation of blood in the colon, analogous to the ecchymoses in the skin, and that this had caused the membrane to be exfoliated. The scurvy symptoms disappeared rapidly under the administration of orange-juice and the child is now well.

DERMOID CYST REMOVED FROM A YOUNG CHILD.

DR. JOHN F. ERDMANN: I recently saw a child, one year and one month old, who had a small tumor above the left external angle of the frontal bone, directly over the outer edge of the orbit. It was the size of a filbert, and was movable only in a transverse direction, being evidently partly bound down by adhesions, etc. A tentative diagnosis of dermoid cyst was made. The tumor, subperiosteal in position, was removed and proved to be a cyst filled with cheesy and fatty matter containing half a dozen hairs from one-half to three quarters of an inch long.

Not long ago I was called to a see a young man, twenty-two years of age, who was suffering from appendicular colic, this being his fifth or sixth attack. All the evidences of acute appendicitis were present. The peculiar feature of the case was the fact that the pulse-rate was slow, only 55, in spite of a subnormal temperature, 97° F. The former, however, was of good volume and the general facial expression was not that of shock. Palpation revealed an appendix about as long and as large as my middle finger. During the next twenty-four hours the pulse increased five or six beats per minute, and the temperature became normal. At the end of forty-eight hours the pulse was only 68, a condition of tachycardia with appendicitis. Symptoms having moderated operation was advised at a later date. A week later I opened the abdomen and found an appendix 3½ inches in length with a stricture 2 inches from the tip, and a large mucus inclusion. The patient made a good recovery.

DR. C. A. LEALE then read the paper of the evening, entitled

SEROUS CEREBRAL APOPLEXY.

This he described as a condition characterized by the rapid effusion within the brain or its membranes of the serum from the blood circulating within the cranial cavity. It may also be associated with a rupture of a blood-vessel and extravasation of blood, in which case it becomes one of serosanguinous apoplexy.

When simple, idiopathic apoplexy occurs not a drop of blood escapes, only serum is found, and there are apparently no other pathological evidences present in the brain or the surroundings; or a general cerebral edema may be present, similar to the "wet brain" of the paretic, due to interstitial effusion of serum and atrophy of the brain to make place for the serum. A sudden increase of this effusion may be caused by cerebral congestion, intense mental strain, great emotion, rapid dilatation of the stomach, etc., and sudden unconsciousness, or profound coma may supervene. If the patient be promptly and properly treated, he may quickly recover, or he may gradually decline until death ensues. The first symptoms usually noticed are, profound nausea accompanied by attempts at vomiting, when the contents of the stomach may be sucked into the larynx or trachea and cause suffocation. In serous cerebral apoplexy the patient falls suddenly, the face becomes pale and the hands cold and clammy; or in exceptional cases of the cyanotic type, the face becomes red, and the blood-vessels turgid. In some cases the brain retains its power, but usually its function is impaired and unconsciousness follows. In others cases there may be such a degree of cerebral edema and localized intracranial pressure that hemiplegia or general paralysis follows. The great danger in serous cerebral apoplexy is that the feeble heart will cease to continue action. Therefore the head should be kept low, the body at rest, and moist heat should be applied to the brain. If necessary forcible respiration must be employed. With this treatment the patient will usually so far recover that in the course of an hour he can be moved to a place of comfort, if still kept continuously in a prone position.

The author cited several cases of serous cerebral apoplexy, and one in a man, sixty years of age, who was suddenly stricken with serosanguineous apoplexy while quietly reading. He immediately became unconscious and soon passed into a state of profound coma. The condition of the patient was alarming and did not differ much from that of a man suffering from simple serous cerebral apoplexy. The man died without recovering consciousness, and an autopsy showed a very minute rupture at the circle of Willis. The opening was so small that it seemed almost impossible that death could have been caused by the small amount of blood extravasated. But in addition, a large quantity of serum was found at the base of the brain, and to the presence of the latter was attributed the profound coma which preceded and was the direct cause of death.

Cases of serous and sanguineous cerebral apoplexy are of frequent occurrence and are attributed by the author to heart and kidney diseases, to the conditions under which business men of the present generation live, and to the rush, worry, and mental strain to which they are subjected. He emphasized the importance of examination of the eyes, as premonitory symptoms of the conditions may there be indicated weeks before an attack occurs. These are shown by redness of the conjunctivæ, involuntary tears running down the cheeks, and increased intra-

ocular pressure. He considers such an examination of greater importance than urinalysis.

DR. EDWARD S. PECK: In regard to the ocular and intra-ocular symptoms which have been emphasized by the author, there can be no doubt that these exist. I have made a few examinations of the fundus of the eyes in these cases and have found a circumscribed perioptic effusion nicely limited to the region about the optic nerve. The condition is not an optic neuritis or an inflammation of the retrobulbar portion of the optic nerve, but in appearance is more like a hyperplasia of the retina itself. Usually, vision is not at first interfered with. The condition, as a rule, is present in both eyes and ultimately ends in optic-nerve atrophy. Some years ago I saw a man who was suffering from Bright's disease. He was attended by a prominent medical practitioner, who had not recognized the disease, and who treated him for nausea and acute dyspepsia. I examined his eyes and found this very marked infiltration about the optic nerve, together with the peculiar condition of the nerve stem and macula, and gave the opinion that the man had only a short time to live. In two weeks he was dead. In two other cases I was able to predict early death after making an examination of the eyes and noting this condition. One of these cases was an acute Bright's disease, and the other a serous apoplexy.

DR. S. N. LEO: I have seen many cases of cerebral apoplexy in people of advanced life, and there is no doubt that the premonitory symptoms referred to in the paper are often overlooked. I recall having made an autopsy in a very interesting case at the Colored Home some years ago. Two of the inmates had had an altercation and it was alleged that the dead man had been violently struck on the head by his comrade. I found a magnificently developed man, fifty nine or sixty years of age, but there was no mark or abrasion on his head or anywhere else on the body. As it was said that the man had bled from the ears I thought there might possibly be a fracture at the base of the skull. I made an incision well down below the occipital protuberance; the skull was exceedingly thick. After I lifted the pia mater and reached the arachnoid I noticed quite a large blood-clot under the pons, and another under the optic tract. Both were quite hard, showing that they had been formed some time. In addition I observed an immense effusion in each ventricle. There was no sign of a fracture. It was further found that the man had advanced Bright's disease. The only conclusion which could be reached was that the man had died of an attack of apoplexy, such as has been so graphically described by Dr. Leale. I am of the opinion that the condition is largely superinduced by advanced disease of the kidney and by senile degeneration. I do not think, however, that the short-necked man is especially apt to have apoplectic seizures.

DR. ROBERT NEWMAN: We have all seen the cases described by the author. The serous form of the disease is not so dangerous as the sanguineous because in the former there is no blood-clot to be absorbed. Many of the patients recover without treatment. I do not attach much importance to the premonitory symptoms for the reason that the attacks occur suddenly and unexpectedly, as a rule. In regard to the treatment of sanguineous apoplexy, it is doubtful if much can be done. Rest and efforts of Nature will do most. However, I would like to ask the author whether he thinks that the iodid of potassium has a good effect in promoting absorption. In these cases the prognosis largely depends upon the degree of paralysis which usually exists to a greater or less extent.

DR. J. BLAKE WHITE: In my experience it generally occurs that the serous form of apoplexy manifests itself more slowly than the sanguineous variety. The brain is tolerant of a slight degree of effusion, and the symptoms become alarming or fatal in proportion to the amount of effusion and its interference with function. I agree with Dr. Leo that short-necked individuals are not especially prone to this type of apoplexy but rather to the sanguineous or mixed variety. It is usually seen in persons broken down by chronic disease and in a cachectic condition occurring as a secondary affection. An ophthalmological examination I can understand would assist very much in making an early diagnosis in these cases, and I am in accord with the views of the author that good results might follow if this precaution were taken.

DR. ROBERT H. GREENE: I would like to say a word as to the prevention of most forms of apoplexy. It seems to me that heredity plays a strong part in the causation of this condition, for in most cases the parents of the patient have suffered from atheromatous changes in the blood-vessels at an early age. These changes often take place at an earlier age than is required by the laws of Nature for one reason, because individuals are so apt while perhaps exercising their brains to exercise their bodies too little. If persons who are predisposed by heredity to this condition would exercise every day methodically to the point of perspiration, their arteries would not break down as early. It is an established fact, determined by microscopical examination, that these degenerative changes begin in the muscular coat of the blood-vessel.

DR. S. H. DESSAU: In regard to the differential diagnosis of serous and sanguineous apoplexy, I would like to ask the author if hemiplegia is ever present in the former condition, or whether it is pathognomonic of the more severe form of apoplexy only. As the treatment in each is different, it is rather important that the two conditions be differentiated.

DR. J. H. FRUITNIGHT: The term serous cerebral apoplexy is seldom used nowadays and modern writers have omitted it from their books. In sanguineous apoplexy a change has previously taken place in the arteries, usually as the result of age, but not always. "A man is as old as his arteries" is a trite saying for even in young men we see changes in the arteries as a result of syphilitic degeneration, the well-known syphilitic endarteritis which often terminates in cerebral apoplexy. It seems to me that serous apoplexy may be considered rather as the result of a toxemia and occurring most frequently as a concomitant of the so-called uremia of chronic nephritis.

DR. A. M. JACOBUS: I desire to ask the author whether there are any records of autopsies made in cases

of serous cerebral apoplexy, and, if so, whether or not evidences of cerebral hemorrhage, embolism, or thrombosis were found. I would also like to know what are the differential points in diagnosis between the so-called serous cerebral apoplexy and the other forms.

THE PRESIDENT: The paper contains many interesting points. I agree with Dr. Greene in what he has said about heredity being a causative factor. I was especially impressed by the truth of this some five or six years ago when I saw in consultation a case of this kind. The patient was a middle-aged man, and upon inquiring into the family history I learned that five of his brothers had died suddenly at or about the age of forty-eight. I predicted that he would not live more than twenty-four hours, and such was the case.

I would like to hear the author say something about hemiplegia in these cases, and also in regard to the use of iodid of potassium to favor absorption, as suggested by Dr. Newman.

DR. LEALE, in closing: In regard to treatment, I find that no remedy acts so well in relieving this condition as elaterium. It has a marked hydragogue effect, and causes a rapid pouring out of serum into the intestinal tract, and thus relieves the congestion in the brain. Rapid resorption of the serum then follows from all the cavities in which the serum lies. I have known two or three gallons of fluid to pass from the gastro-intestinal tract. Sometimes elaterium causes vomiting of fluid in consistency very much like the rice-water discharge of Asiatic cholera. The iodid of potassium, or the iodid of sodium, which is better borne, may be administered at a later period to complete absorption. Pilocarpin, which will produce profuse sweating within eight minutes is sometimes beneficial, but the objection to its use in serocerebral apoplexy is that it depresses the heart. It should never be employed if there is much intracranial blood-pressure with atheroma. The all important pneumogastric nerve must always be considered and the teachings of physiology remembered.

Hemiplegia, as a rule, does not occur in serous cerebral apoplexy, for the reason that in this condition there is an equalized pressure upon the brain and not a localized pressure at any one point, as is the case in cerebral hemorrhage. But there may be a modified form of general paralysis, which generally passes off within twenty-four or thirty-six hours after the patient has been stricken.

I have known a man stricken with serous cerebral apoplexy to remain unconscious for hours, yet be apparently well within a week.

The term serous cerebral apoplexy is an old one and recent writers continue its use.

We live in a time which produces men who die suddenly. The New York business man lives under a tremendous pressure. Merchants, lawyers, clergymen, and doctors are all struggling for an existence and eminence. The pressure of life is so intense and the mental exertion is so great that it is easy for me to understand why we see so many cases of serous cerebral apoplexy and sudden death.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held Thursday, May 18, 1899.

THE President, DR. WILLIAM H. THOMSON, in the Chair.

The first paper of the evening, on

RECENT METHODS OF LOCAL ANESTHESIA FOR MINOR AND MAJOR SURGICAL OPERATIONS,

was read by DR. ALEXANDER B. JOHNSON. He said that the main advantage of local over general anesthesia is that it involves less risk. If local anesthesia could always be made absolutely painless this would be true. The shock and worry of operation during consciousness, however, and the pain it gives during and after operation are serious objections in many cases.

In acute inflammatory cases the application of local anesthesia means a good deal of pain and there is a dull ache afterward that seriously disturbs the patient. In addition the infiltration of the tissues by the anesthetic may interfere with primary union. At times the dissection of the tissues during the operation must unexpectedly be carried deeper than was anticipated, good anesthesia is hard to secure in the depths of the wound, the surgeon is disturbed, and his technic and the completeness of the operation is apt to suffer.

At times, moreover, patients have an idiosyncrasy for cocain and excitement develops even after the employment of but small amounts. It may develop without warning, and this point must be carefully borne in mind by the surgeon. When marked idiosyncrasy exists, even small operations cannot be performed with local anesthesia, but even in milder forms the field of application for local anesthetics is very limited. It was thought that most of the pneumonia that developed after operation would disappear on the use of local instead of general anesthesia, with its consequent irritation of the pulmonary mucous membrane. This, however, has not proved to be the case. Though more limited in application than was hoped at first it would be, local anesthesia is of distinct service. It may be employed with advantage in the surgery of the skin, the hand, the foot, the mucous membrane, the eye, for such operations as the wiring of the patella, the tapping of the knee-joint, urethrotomy, the resection of a rib, and the like. In major operations it is apt to impair operative technic and unless there is some special reason it should not be employed. In gastrostomy and in the operation for cancer of the esophagus, when it is necessary to avoid vomiting afterward, local anesthesia may be properly adopted. The speaker had seen cruel operations performed under local anesthesia, but it requires the utmost coolness on the part of the operator, and a certain hardness of feeling not often possessed by the surgeon.

As to the means for local anesthesia ethyl chlorid serves a good purpose in superficial work, for skin incisions, or for needle insertions. The two great local anesthetics for introduction under the skin are cocain and eucain. The latter is growing in favor. For mucous membranes, as in the mouth, it is better to paint the site of operation with a strong solution, using a camel's-hair brush, rather than to spray the whole cavity. Symptoms

of intoxication often develop suddenly and without warning and are to be guarded against. In the urethra, local anesthesia may be secured by irrigation, the urethra being filled with a 5-per-cent. solution, which is allowed to remain for one minute. It is claimed that half an ounce of a 5-per-cent. solution will produce satisfactory anesthesia of the bladder, but the speaker said he had had no experience with this procedure. In the urethra special care is needed to guard against intoxication. Around the face sudden symptoms of intoxication sometimes develop. He had once seen 5 minims of a 4-per-cent. solution introduced into the supra-orbital region for neuralgia produce alarming symptoms. In another case 6 minims of a like solution had a similar effect.

In acute inflammation the pain is lessened by injecting the anesthetic around the inflamed area. In operations upon the hands and feet a rubber ligature should be applied at the wrist or ankle or on the fingers or toes. The free bleeding afterward removes the cocain and much more of it can be used. It must be remembered, however, that the application of a ligature is painful and gives rise to bitter complaints afterward. Injections made over the course of a nerve, as at the side of the finger, make the area of its distribution anesthetic.

Schleich of Berlin adds the well-known anesthetic effect of tension to that of the drugs employed. His solution contains a minimal quantity of cocain and a certain amount of morphin, besides common salt. The morphin, however, is of no advantage as it has no local anesthetic effect. There are certain objections to Schleich's method, as the number of needle punctures necessary are annoying to the patient and bothersome to the surgeon. The forcing in of fluid into an inflamed area may lead to the spread of infection and the tension on the tissues conceals anatomical details.

Eucain solutions have the advantage over cocain solutions that they may be boiled. Cocain breaks up if heated to the boiling-point. There are some other substances that have been used and recommended but clinical experience with them is not extensive enough to justify a definite conclusion as yet as to their efficiency and value. Among them the most prominent are eucain "a", certain derivatives of guaiac and orthoform. None of them is capable of replacing cocain or eucain.

In the discussion which followed DR. HOWARD LILIENTHAL said that two years ago he would have agreed with the essayist as to the very limited field there is for the use of local anesthesia. Now, however, he felt differently. He learned to distrust cocain but now trusts eucain. As for pain with local anesthesia, patients often fear that they are about to be hurt and complain very much. The best proof, however, that they do not suffer actual pain is that they do not move. Cocain is especially dangerous because it depresses the heart. He had seen 4 minims of a 5-per-cent. solution injected for the removal of a wart produce serious symptoms. Eucain, on the contrary, is a heart stimulant. Five grains may be used in the case of a feeble subject and as high as 10 grains has frequently been used without evil result. Eucain causes an unpleasant, painful feeling afterward. This may be relieved by packing the wound with orthoform gauze. That operations under eucain are painless, the fact that physicians have come back to have boils opened under it seems sufficient proof. A method not sufficiently employed by surgeons, though well known to dentists, is the cataphoresis of cocain. He had had sensitive dentine removed in this way absolutely without pain.

Eucain should not be employed with a constrictor as it is liable to cause necrosis. For even serious operations eucain local anesthesia suffices very well. In three cholecystomies no pain was felt except that occasioned by pulling on the gall-bladder in bringing it up to attach to the skin incision. In operations for strangulated hernia the drug does very good service and he had used it very satisfactorily in operations for the radical cure of hernia.

A hypodermic injection of morphin, ¼ to ⅓ of a grain according to the patient's condition, relieves the mental strain and should be given a few minutes before the operation. If in the course of the dissection a nerve is met with a tiny drop of the solution should be injected directly into it. There need be no hesitation to give chloroform if it should be considered advisable after having tried eucain as the drug is stimulant not depressant.

DR. BATES said that cocain does not always produce local anesthesia satisfactorily for eye work. In operations on the muscles especially, pain is often complained of. When anesthesia is good a blanched appearance follows the use of cocain. In certain patients hyperemia of the parts developed and in these pain would always be complained of. In most of these cases the use of extract of suprarenal capsule used in conjunction with the cocain would produce the desired capillary closure with blanched appearance and anesthesia. The mental condition is important, however, and in excitable, neurotic patients, even with extract of suprarenals one is not always sure to obtain good local anesthesia.

DR. JOHNSON said that he is not a pessimist as to local anesthesia. He uses it every day in dispensary and office practice. There is a good deal of pain associated with the use of local anesthesia and especially after the operation is over. As to neglecting a patient's complaints there are surgeons who can and still do justice to their work, but he cannot, and a squirming, complaining, patient makes him hurried and not as exact and careful as he would otherwise be.

The second paper, entitled

FURTHER EXPERIMENTAL RESEARCHES ON THE EFFECTS OF DIFFERENT ANESTHETICS UPON THE KIDNEYS,

was read by DR. ROBERT COLEMAN KEMP. It contained the report of a series of exact observations upon the kidneys of animals in which an oncometer had been used to determine the varying size of the kidney and the amount of blood going to it at any time, while section of the ureter showed the amount of urine being excreted. Ether gave a characteristic oncometric curve with a persistent fall in blood pressure in the kidney and diminution of the amount of urine passed. This was markedly different from the effect of any other anesthetic and even in anesthetic mixtures the presence of ether could be de-

tected by its effect on the oncometric curve. As the ether was pushed urine became less and less in amount and more and more albuminous, and finally suppression of urine resulted.

Chloroform depressed the heart and consequently the kidney circulation, but albumin did not occur so abundantly and the decrease in urine was only proportionate to the decrease in general blood pressure. There was no specific effect of the chloroform upon the kidney as was the case with ether and urinary suppression did not occur.

The A.C.E. mixture, in the proportion of 1, 2, and 3 by volume of alcohol, chloroform, and ether, acted differently according to circumstances. If air were freely admitted then the ether seemed to be without effect, and only the same effect as that produced by chloroform was noted. Without free admixture with air the ether kidney developed.

Schleich's anesthetic mixture was found to be especially severe on the kidneys, an emphasized ether kidney resulting very soon, with suppression of urine. No variation of this result was noted when curara was administered. Nitrous oxid had the least direct influence. The circulation was slowed but immediately restored on withdrawing the gas. No specific effect was observed on the kidneys, and the effect noted was evanescent with rapid return to normal.

Anesthol, Dr. Willy Meyer's proposed variant of Schleich's anesthetic mixture, is especially dangerous. Bloody urine occurred and complete suppression of urine set in very soon after the beginning of the anesthesia. The blood-clots could be traced up into the pelvis of the kidney so that the irritation was of the secreting substance of the kidney.

His conclusions were as follows: As far as their effect upon the kidneys are concerned Schleich's anesthetic mixtures and anesthol are most dangerous, ether comes next, producing a specific effect on the kidneys, chloroform is less hard on the kidneys, and nitrous oxid affects them least. Some of these conclusions have been confirmed by clinical experience. After an anesthetic more than half the patients have albuminuria when there was none before. Lawson Tait has pointed out that with chloroform the danger from the anesthetic was immediate but with ether it was subsequent in the danger from pneumonia and uremia.

The third paper, entitled

TECHNIC OF ADMINISTRATION OF ANESTHETICS TO PATIENTS SUFFERING FROM KIDNEY TROUBLES,

was read by DR. THOMAS L. BENNETT. He does not consider a passing albuminuria even with a few hyalin casts as especially significant. They are not always due to the anesthetic but may be found also after operations where no anesthetic was employed. Exposure of the patient during an operation seems to have this irritant effect upon the kidneys and great care should be exercised in keeping the patient covered especially when a kidney lesion exists. Then the patient should be transferred as soon as possible after the operation to a heated bed in order to arouse the skin to action. Operations on the genito urinary tract seem to affect the kidneys reflexly and require special precautions as to anesthetics and care for the warmth of the patient.

In the order of their influence on the kidneys anesthetics may be arranged about as follows, beginning with the least harmful: (1) Local anesthesia. (2) Nitrous oxid with oxygen. (3) Nitrous oxid with air. (4) Chloroform. (5) Ether. Of any of the general anesthetics in a nephritic patient the smallest quantity possible should be used. Only analgesia, not complete anesthesia, should be sought. The conjunctival reflex should not be abolished, pupillary activity should remain, and other reflexes, and even soon slight pain, may be allowed to be present.

Nitrous oxid is the least harmful but the state of asphyxia it produces causes a passive congestion. If air is mixed with it the asphyxia is less, but the anesthesia is not so good. When mixed with oxygen, as Hewitt has suggested, it is least harmful. A special bag, with a diaphragm and a mixer for the two gases, is employed and the effect is very different to that seen when ordinary nitrous oxid is employed. It must be confessed, however, that certain subjects fail to be brought under the influence of the anesthetic sufficiently to permit of surgical operations. In some cases, too, vomiting occurs after nitrous oxid, and the after suffering is often great because of the prompt revival from the anesthesia.

DR. MELZER, in the discussion, said that he considers the action of ether upon the kidney scarcely as a specific one. Caffein has just the opposite action upon the circulation to that of ether. There is first a fall of blood pressure and then a rise, so that it becomes an interesting question as to whether caffein would compensate for ether. In case of suppression of urine, he has found salicylate of soda effective in restoring urinary secretion. The double salicylate of caffein and soda would seem to be especially indicated.

DR. ABBE said that despite the experimental results obtained he would trust to ether as an anesthetic. In a number of cases examined at St. Luke's Hospital albumin and casts had been found in the urine after ether anesthesia, but they were hyalin casts and disappeared after a day and practically no significance should be attributed to them. Even repeated administration of ether does not produce nephritis, and no lasting damage seems to be done to the healthy kidney. He also has seen good from the use of salicylate of soda in urinary suppression. In a case of pyuria he saw excellent results follow its administration. While in certain cases with only diminished urinary secretion not much effect seemed to follow its use he thinks it well worth further careful clinical observation.

It would be unfortunate if a diminished confidence in ether should follow the observations made in these physiological studies for ether is our most trustworthy anesthetic. The exposure of the patient during operation is important in its influence on the kidneys, but not the anesthetic ordinarily.

DR. J. E. KELLY said that mixtures of anesthetics seem to combine all the disadvantages of their ingredients. Some of the more recently suggested mixtures would seem theoretically at least in this regard to be per-

fect death-dealers. As for himself he prefers chloroform as an anesthetic. He has seen two deaths from chloroform anesthesia both of which he considers could have been justly attributed to careless anesthetists. He has seen five or six deaths in ether anesthesia, and only once was the anesthetist at fault.

DR. KEMP, in closing the discussion, said that an important element in the effect of an anesthetic upon the kidneys is the susceptibility of the patient to irritants—his personal equation. For this it is advisable to know some details of his previous life and his tendency to react to exposure and the like.

REVIEWS.

THE SERUM DIAGNOSIS OF DISEASE. By RICHARD C. CABOT, M.D. Physician to Out-Patients, Massachusetts General Hospital, Boston. New York: Wm. Wood & Co., 1899.

THIS volume adds little that is new to our knowledge of serum diagnosis; nor can it be regarded as a very practical laboratory guide. The author plainly disavows any such claims for his work. He states in his preface: "This book is nothing but a compilation. Its aim is to bring together in convenient form the results of the immense amount of work which has been done in serum diagnosis since 1896." With this sole purpose in view the author has presented in a clear and condensed form the results of the work of himself and others in the experimental and clinical study of serum reactions in typhoid fever, cholera, leprosy, tuberculosis, etc., these results being conveniently classified, compared and reviewed. The review is not very critical, however. The greater part of the book is devoted, as might be expected, to the Widal reaction in typhoid fever.

Both as a condensation of the literature of the subject and as a bibliographical reference, the work is of distinct value. It is well printed and freely illustrated.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART A. HARE, M.D. Vol. II. June, 1899. Philadelphia and New York: Lea Brothers & Co.

THE second number of the new quarterly shows that the high standard already established and so well justified by the contents of the first volume is maintained and further substantiated. Dr. Coley presents an excellent up-to-date review, especially of the three subjects of greatest practical interest in abdominal surgery just at present: the surgery of the gall-bladder, of radical operations for hernia, and for appendicitis. In the surgery of the biliary tracts the recent work of Rehr in Germany and Mayo Robson in England has been most encouraging. It is evident that a great development in biliary surgery is about to take place and that active interference early in the case will replace the expectant methods that have been adopted up to this time.

In the review of the recent work on the radical cure of hernia Kocher's methods and results especially are detailed and commented on. In the last five years none of his patients have died and in no case in which Kocher himself has operated in recent years has there been a relapse.

The review of the literature of appendicitis is very interesting especially because it brings out the fact that the subject is now as much discussed abroad as it has been here in America for the last few years. Czerny's view that the first attack of appendicitis belongs to the physician is the expression of an ultra conservative, as practically all are agreed that appendicitis is now from the very beginning a surgical affection.

Dr. Clark in "Gynecology" presents a very interesting review of the recent experimental work done on the transplantation of the ovaries. There would seem to be possibilities ahead in this subject that may lead to important and very practical developments. With regard to that very interesting subject, the occurrence and prevention of ventral hernia after operation, some very striking facts are brought out. For instance, it is clear from Abel's investigation of the case of Professor Zweifel, the head of the the Gynecological Clinic at Leipzig, that a number of prejudices are unsubstantiated by actual experience. Abel succeeded, with what painstaking patience may be well imagined, in getting the after histories of all but five of nearly 700 patients. From his statistics it would appear that the wearing of a bandage has absolutely nothing to do with the prevention of hernia, and the time of resumption of active work by the patient stands in no causal relation to the production of the lesion. There is abstract of the discussion between Behrens of Berlin an and Professor Neisser of Breslau on the treatment of gonorrhea in women in which Neisser's plea for active germicidal treatment rather than that by simple astringents is commended and his recent declaration of faith in ichthyol for this purpose commented on favorably.

We are tempted to say more about the good things in this number and cannot close our review of it without at least a reference to Dr. Stengel's very interesting abstract of recent work on the relations between diabetes and glycosuria and Dr. Jackson's excellent review of the recent literature of the toxic amblyopias.

URINARY ANALYSIS AND DIAGNOSIS by Microscopical and Chemical Examination. By LOUIS HEITZMANN, M.D. With 108 Original Illustrations. New York: William Wood & Co., 1899.

THE meritorious feature of this new manual of urinary analysis is its illustrations, all of them original. The plates showing the different forms of cells that occur in urine, with their probable origin, are especially interesting. The clusters of fattily degenerated epithelial cells, with their abundant content of bacilli and cocci, which constitute smegma, and which occur so often in the urine of females, have not before been so fully described or so characteristerically illustrated as they deserve. There is, perhaps, a tendency noticeable in the book to claim too much for the possibilities of recognizing microscopically the site of origin of the various forms of epithelial cells, but the fault is in the proper direction, for, as a

rule, diagnosticians do not make sufficient use of the histological indications furnished them by the various cells that occur in urinary sediment. In this respect the book is a distinct advance on handbooks of urinary analysis generally. The characteristic microscopic picture of the urinary sediments of such conditions as acute and chronic prostatitis, of spermatocystitis or seminal vesiculitis, and of chronic catarrhal vaginitis are interesting and suggestive, even though one may not be prepared to go as far as the author in enthusiastic claims for the diagnostic usefulness of the microscope in these conditions. On the whole, the book is one of the best of its kind and is thoroughly up to date.

MATERIA MEDICA AND THERAPEUTICS. An introduction to the Rational Treatment of Disease, for the Use of Students and Practitioners of Medicine. By J. MITCHELL BRUCE, M.D., F.R.C.P., etc., Physician and Lecturer on Medicine at Charing Cross Hospital, London. Sixth Edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co., 1899.

THIS work appears in the same compact form which (together with its scientific value), made it in the first edition so popular among American, as well as among English, students. Changes have been made in the text to adapt it to the new British pharmacopœia and to make it representative of recent advances in our materia medica. There is no reference, however, to those of our newer drugs which, though unofficinal, are well deserving of mention in a book of this character.

The discussion of the various remedies is admirably divided; *e. g.*, in the separate treatment of "immediate local actions," "actions on the blood and specific actions," "remote local actions," etc. We cannot bestow as much praise on the general grouping of the remedies. We believe that a change from the chemical and botanical classification to the more rational arrangement according to physiological effects would have marked a distinct improvement in the new edition over the first one. The adopted subdivision robs the work of much of its value as a reference for the physician, and fails to present the pharmacopœia in an impressive *therapeutic* review to the overtaxed memory of the student.

The text, however, is interesting, so far as that of a condensed hand-book on materia medica can be. Unessential details are omitted and salient facts are tersely and unequivocally presented. One of the most attractive features of the work is the interesting and scholarly division devoted to general (and we might add special) therapeutics.

ELECTROHEMOSTASIS IN OPERATIVE SURGERY. By ALEXANDER J. C. SKENE, M.D., LL.D., Professor of Gynecology in the Long Island College Hospital of Brooklyn, etc. New York: D. Appleton & Co., 1899.

THE author of this book has been an advocate of electric hemostasis in surgical operations since he first learned its usefulness. In the present work he presents an elaborate review of the subject including a description of the essential instrument and macroscopic and microscopic examinations of tissues burned with the electric cautery. It is this chapter which will most interest surgeons since it gives the *raison d'être* of this method of controlling bleeding in surgery. Dr. Skene shows that by means of the cautery the lumen of an artery becomes entirely obliterated; that after two hundred trials no secondary hemorrhage ensued; that an artery a quarter of an inch in thickness was reduced to about one-twelfth of an inch in thickness and that the tissues were rendered amorphous by the heat and pressure. The treatment of friable tissues which cannot be ligated, and the closure of canals lined with mucous membrane, and the sterilization of the parts as well, can be accomplished better by this means than any other. The author finds that pain is diminished by this method of hemostasis on account of the devitalization of the nerves severed. The remainder of the book is taken up with chapters on the use of the electric cautery for hemostatic purposes in the various branches of surgery, and two chapters on aseptic and antiseptic surgery. As a pioneer in this field of surgical technic the book is interesting and deserves careful reading by every man engaged in surgical work.

THERAPEUTIC HINTS.

The Addition of Chloroform to Alcoholic Solutions of Bromoform renders them miscible with water in any proportion, whereas the bromoform would otherwise be precipitated by the water. For instance:

℞	Bromoformi	*m.* xviii
	Chloroformi	*m.* xii
	Rum q. s. ad.	℥ ii.

Application to a Cancerous Cervix.—

℞	Orthoformi	gr. xv
	Ac. arseniosi	gr. iss
	Spiritus, Aquæ aa	ʒ ii.

M. Sig. Saturate a tampon with this solution and apply to cervix.

For Pertussis.—The following is the formula prescribed by MORITZ COHN of Hamburg from which he claims excellent results:

℞	Bromoformi	*m.* iii–xii
	Absolute alcohol	*m.* x–xl
	Pulv. acaciæ	gr. lxxx–ʒ v
	Syr. aurantii	℥ ss
	Aq. dest. q. s. ad.	℥ iv.

Dissolve the bromoform in the alcohol, triturate carefully with the acacia and gradually add the syrup and water. Sig. One to two teaspoonfuls every two hours. Keep in a dark bottle and shake well before using.

For Infectious Infantile Diarrhea.—

℞	Laudanum of Sydenham	gtt. ½
	Ac. hydrochlorici dil.	gtt. ii
	Sugar water	ʒ v.

M. Sig. Give at one dose. Repeat several times a day if indicated.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, AUGUST 5, 1899. No. 6.

ORIGINAL ARTICLES.

THE OCULAR AND ORBITAL SYMPTOMS OF LESIONS OF THE FRONTAL SINUS.[1]

BY ROBERT SATTLER, M.D.,
OF CINCINNATI, OHIO.

SUGGESTIONS drawn from carefully conducted clinical studies, with the disclosures of surgical experience, have led to and clearly defined a rational and eminently practical surgery for these obscure lesions of the sinuses of the frontal bone. The pathologic processes which invade these pneumatic cavities are better understood than formerly. The acute ones disclose their nature with almost certainty of diagnosis. Their clinical characteristics and the indications for surgical intervention can, in exceptional cases only, be misinterpreted. Chronic lesions are of far more frequent occurrence. Their course is marked, almost without exception, by interminable chronicity, with clinical attendants so meager or uncertain that error in diagnosis is frequent. The reasons for this are evident. Those which result from transplantation of pyogenic products from the adjacent nasal cavity — which are again the most frequent—and those as well which are due to direct extension along the mucous lining or bony walls from intranasal disease along the connecting channel or frontal canal, occur with especial frequency among male adults. These air spaces have even during early adult life reached spacious dimensions and their bony encasement is fortified as age advances. The low grade of inflammatory activity which commonly attends such processes and the compensatory hypertrophy or sclerosis of the walls which is thereby excited combine to decree for the incarceration of pyogenic matter, granulation tissue; inspissated pus, etc., an almost latent course with uncertain or absent clinical features.

These are among the causes why recognition of chronic lesions is wellnigh impossible during the early stages or until more tangible evidence of perforation of the outer wall with undermining of the periosteum and other symptoms point to their real nature. Again, in consequence of the constant choking with granulation tissue or other pathological products, the cavity is abnormally distended and immense rarefaction, with atrophy of the bony walls, as well as of the mucous lining, results, accompanied by partial absorption or desiccation of their contents. This larger cavity, with thinner walls, is completely shut off from all communication with the nasal cavity through the infundibulum or fronto-nasal canal. Disturbance of its physiological purpose follows and occasions constant distress, with often, also, violent explosions of neuralgic pain over this locality. It may also happen that increase of thickness or hyperostosis of the external walls results, especially as a final expression of a chronic, latent, lesion. Not infrequently is this attended by violent outbursts of neuralgic pain without local or inflammatory symptoms. In such cases, surgery, which may suggest itself and be practised as an empirical measure for diagnostic means, or in search of pus, even in the absence of any positive assurance of its presence, reveals only bone hypertrophy. Why this should cause, in some cases, violent suffering and in others none, is as unexplained as are the vagaries of other similar lesions of the temporal bone. We also meet with the same negative expression in other secondary lesions. The growth of osteophites or exostoses within the sinus with the latter enormously distended, affords only another illustration. With the exception of the increasing deformity, pain or other subjective discomfort remains absent.

It has already been stated that it is during early and middle adult life that the original sinus lesion, or the final expression of such lesion, is met with. The discovery of the real character of such resulting or secondary lesion, however, is possible only after the surgical intervention which becomes expedient or necessary reveals it.

This does not imply that lesions with a similar latent course are not met with also during the earlier years of life. Experience has taught me, especially my earlier observations, that the cases of so-called periorbitis and unquestionably also, a goodly share of the cases of caries of the margin of the orbit, in strumous or rachitic children, are really expressions of frontal sinus disease. The earlier stages of the lesion are latent, as in the older subjects, but owing to the thinness of the bony enclosures and the small size of the cavity perforation occurs more readily and almost as a necessary sequence.

The temporal angle of the sinus is a not infrequent location for perforation by the retained contents, and a trail of burrowing pus follows of nec-

[1] Read before the Ohio State Medical Society, at Springfield, Ohio, May 12, 1899.

essity the contour of the orbital margin and its outlet or sinus eventually opens near the outer canthus. This remote location, so far removed from the original starting point, is not at at once associated with a sinus lesion. It is a disclosure of surgery and a noteworthy triumph as well, which has proved the truth of this statement, and has enabled us to treat these obstinate cases with far greater satisfaction and the avoidance of unsightly deformity.

Some fifteen years ago I began a systematic and careful study of all cases belonging to this category. The first attempts of exploratory surgery in chronic cases with latent course, in which a retention of pus or other inflammatory products was surmised, were made with old-fashioned drills and trephines. Brief mention of one of the first cases is made, because of its instructive lesson:

A lad, aged twelve years, had suffered for years from frontal and general headache. For some time his parents had noticed an increasing prominence of the region over the frontal sinuses and inner, upper margin of the orbit. Nasopharyngeal catarrh was present but there were no unusual features. The customary local treatment had been tried ineffectually for a long time, without relief of the headache. There was no tenderness over the frontal sinus region nor redness or swelling of the soft parts. Unmistakable bone enlargement, however, was present. Ocular symptoms there were none, except epiphora, which was neither persistent nor annoying. In spite of these negative symptoms the sinus was opened with a drill, which operation, owing to the thickness of the bone was both difficult and tedious. Extensive hyperostosis was found and the sinus was full of pus. Subsequently the other sinus was opened with similar disclosures. Recovery ensued, with complete subsidence of pain.

The point which this brief recital emphasizes is that exploratory surgery, aided and reinforced by modern surgical methods with the use of less cumbersome instruments, affords us an opportunity for the practice of rational and successful surgery.

Taking up, briefly, the especial purpose of this paper, the ocular and orbital symptoms of the more uncommon chronic lesions, it must again be stated that, for an indefinite period, such lesions or their final expressions may run an entirely latent course both as far as local and constitutional disturbances are concerned.

Orbital Symptoms.—Among the first tangible evidences are diffused and localized tenderness, without redness or swelling over the affected region. This is generally unilateral as it is rare to find both cavities affected at the same time. This gives way to transitory, painful swelling of the periosteum and bone, often with redness and swelling of the overlying soft parts. These symptoms come and go, lasting generally several days or weeks. Headache now may become general. At the same time there will be observed a characteristic indication, and this is a change of contour of the inner, upper, and in some cases, even of the inferior margin of the orbit. If the lesion is unilateral, and it generally is, the asymmetry of this important part of the face and the change of physiognomy which it entails, point with significance to an existing sinus lesion. If tenderness on pressure or percussion is present, it is even more suggestive of this view.

The most careful rhinoscopic examination fails to disclose more than a chronic catarrhal process which is known to have been present and to which, also, the symptoms due to the sinus complication are assigned. In some cases even, the symptoms of an existing nasal lesion are in abeyance during the progress of the sinus lesion.

If the grade of inflammatory activity remains low, it may happen that a chronic empyema may undergo partial absorption or inspissation and terminate in a contraction of the cavity with increased thickening of the walls; in other words, hyperostosis results. It may also happen at this stage or with the presence of the symptoms referred to, that a spontaneous evacuation through the frontonasal canal into the nose, effects in some cases temporary arrest and in a few, complete termination of the sinus lesion. In exceptional cases, among those first mentioned, in which hyperostosis of the walls takes place and recovery without external perforation results, there comes about as a remote sequence, neuralgic seizures[1] of extraordinary severity and duration. A more frequent result, however, is the yielding of the walls at one or another point. In children this is not infrequently the temporal angle of the sinus, but with them and with adults it is more often the lateral or orbital wall at points near, above, or even below the inner canthus of the eye.

The periorbita in this locality is firmly attached to

[1] This patient, a man aged thirty-six years, had suffered from what he and his physician supposed was intense paroxysms of supra-orbital neuralgia of the right side. Years before he had contracted syphilis but no manifestations of late syphilis were observed. Nevertheless, he had received the most thorough antispecific treatment for several years. The entire frontal region near the margin of the orbit, which was thickened, was the seat of an extensive and marked bone hypertrophy. This swelling was smooth except at the under surface, near the free margin of the orbit where irregularities were discovered. He suffered constantly from pain with exacerbations of more violent seizures at short intervals. Drooping of the upper lid but neither exophthalmos nor lateral displacement of the eyes was present. An exploratory operation discovered most extensive thickening of the bone which was hard and brittle and not vascular. Several fistulous openings in the bone, near the upper margin of the orbit, were discovered, but there was no pus or offensive discharge. The sinus was fully opened. The cavity was small and partially filled with caseated pus. The entire region was ablated, and recovery, though tedious, resulted with complete subsidence of the intense neuralgic seizures.

the bone and is furthermore reinforced by the orbital fasciæ and medial ligament and this explains the resistance which is offered to the burrowing pus. For this reason the dissecting trail is often deflected and pushes its destructive work lower down while its most frequent outlet is under and at the outer or temporal border of the tear-sac. Not infrequently several fistulous openings discharging the contents of the sinus frontalis appear along the orbital margin near the middle or even its outer division.

They may also undermine the periosteum tear-sac, erode the os unguis and superior maxillary of this region and without external perforation discharge their contents into the nose. In particular do we observe this in broken-down syphilitic subjects. In such cases, both internal and external perforation is likely to take place.

Ocular Symptoms. — The earliest ocular manifestations are observed on the part of the eyelids. A serous infiltration of the loose cellular fasciæ of the roof of the orbit dependent upon and associated with the transitory exacerbations of the insidious sinus lesion may interfere with the action of the levator muscle of the upper lid, and also with the superior rectus muscle. Drooping of the upper lid and slight restriction of motion upwards is often observed. Proptosis, due to the same cause, and lateral downward displacement of the globe may also be present, even at this early period. To these symptoms are added an edema of the inner third of the upper lid with dusky discoloration. This, in some cases, is so much like the inflammatory edema and tissue infiltration which attends a suppurating chalazion that it is not infrequently mistaken for this. On the part of the conjunctiva, especially the retrotarsal and ocular divisions, engorgement of the venous channels and frequently chemosis are observed. This is not of inflammatory origin, but is due to obstruction of the outflow of the venous channels. In some cases the upper fornix at this point is evulsed. Pus-trails may cause this and discharge their contents into the conjunctival sac.

The symptom of proptopsis is a variable one and is not in conspicuous evidence even in pronounced cases of uncomplicated frontal sinus disease. In those cases in which a necrosing syphilitic lesion invades the ethmoidal cells and frontal sinus jointly, or all the pneumatic cavities are involved, this is almost uniformly present.

A feature of the exophthalmos accompanying sinus frontalis lesions deserves mention. In common with similar processes of the ethmoidal cells it is subject to great variation. At times it is present and again it disappears entirely. Only in most exceptional cases, in which perforation under the periorbita takes place behind the margo orbitalis and insertion of the orbital fasciæ and medial ligament, and the dissecting trails push backward toward the apex of the orbit, is dislocation of the eye a necessary effect and exophthalmos a conspicuous symptom.

To this rather incomplete description of the clinical features a brief account of a typical case is added in order that it may supplement what may have been omitted:

The patient, a lad aged twelve, had, for several months, complained of general headache, which did not yield to treatment, general and local, and faithfully tried. His parents were healthy, the boy was well developed and free from any evidence which might suggest constitutional disease. Several weeks before he was brought to me he was taken to the family physician who attempted to open what he supposed to be an ordinary hordeolum near the inner border of the upper lid. When he first came to me the asymmetry between the frontal regions of the two sides was unmistakable. The entire inner half of the right upper lid was infiltrated and the skin dusky in color. The movements of the lid were restricted and the palpebral fissure distorted and contracted. The superficial veins of the conjunctiva were tortuous and prominent. Proptopsis, with slight lateral displacement was present, but neither diplopia nor restriction of ocular movements was noted. Functional examination of the eye was perfect and nothing noteworthy, on ophthalmoscopic examination, was observed. The entire inner and upper margin of the right orbit was tender on palpation, but redness was confined to the tissues of the lids. At the point under the tear-sac which appeared more prominent as compared with the other or more healthy side, tenderness on the slightest pressure was complained of. Over the sinus itself, however, it required a much firmer pressure to excite pain. Fever and lassitude, which had steadily increased, were constant. Surgical intervention was practised without delay. It brought unlooked for revelations. The sinus was uncommonly roomy considering the age of the patient, and was crowded with granulation tissue and pus. On the under orbital surface, bone perforation had occurred in several places. The pericranium was extensively elevated and a large trail was discovered, leading under the tear-sac and side of the nose, which corresponded to the point of greatest external tenderness. Recovery was tedious but unattended by complications.

The surgical methods which enable us to explore the sinus frontalis from without for diagnosis and successful treatment are, at present, so satisfactory that few surgeons attempt drainage or exploration

through the intranasal opening. I have long since abandoned this method as uncertain and unsatisfactory, and resort exclusively to the external one with chisel and mallet. Trephines and dental drills are preferred by some surgeons, but the simplicity and ease of manipulation of the method and instruments referred to justly entitle them, in my opinion, to the preference.

SOME SALIENT POINTS IN THE TREATMENT OF HIP-DISEASE.[1]

By B. E. McKENZIE, M.D.,
OF TORONTO, CANADA.

Not only to the orthopedic surgeon but to the general practitioner and the laity is hip-disease a subject of perennial interest. Though this affection has been presented again and again in all its aspects, yet there may be some advantage in setting forth the results of individual study. In doing so the indulgence of the Association is craved if the writer should seem somewhat dogmatic in the assertion of his own opinions. Through a clear-cut statement of his own views his paper will the better elicit the valuable results of the large experience of the members of this Association.

The question may be regarded as settled that when an early diagnosis is made effective mechanical and constitutional treatment is always to be preferred to operative measures. There are few who to-day would adhere to the opinions advocated by Barker in the Hunterian Lectures of 1887. One is scarcely surprised that stimulated by some important advances of nearly twenty years ago surgeons went to extremes in operative work. The most important of these advances were the practice of asepticism and the discovery of the bacillus tuberculosis. Strong claims were made in favor of early operation resulting in speedy cure. Everywhere we find surgeons who believed and who acted on the belief that as soon as a diagnosis was made excision of the joint should be performed, thereby removing the femoral head and all infected tissue, cutting short the course of the disease, forgetting for the moment that they were rarely able to eradicate all the infected tissues. It may candidly be said that all these fair promises held out by distinctively operative treatment were not realized.

Although these patients were sometimes sent home a month or less after the operation, with the wound healed, this seeming to be a most satisfactory and gratifying result calculated to beget a hope that by operative measures alone these subjects could be cured in a short time, yet further observation often showed a recurrence of the disease. Though the greatest precautions were taken, yet untoward results, even death, sometimes followed as the direct consequence of the operation. Even in the cases in which the most favorable course possible was taken it was found that excision of the femoral head in itself was the cause of no slight disability, and in a considerable portion of the cases the focus of disease at the head was not the only one, and subsequently tuberculosis manifested itself elsewhere. There are serious hindrances to the successful accomplishment of the complete eradication of the disease. One of the epiphyses, that most frequently invaded primarily, is so situated as to be entirely within the capsule. Its removal calls for an excision, which in all cases greatly invalidates the joint function, permitting the limb to slide upward in its relation to the pelvis, thus becoming insecure for the purpose of weight bearing. If the primary focus be in the floor of the acetabulum, as it is in a considerable proportion of cases, it cannot be reached without complete excision. On the other hand, if the primary focus be found at an early date at either of the trochanters or in the synovial membrane there is a better prospect of its removal without serious interference with the integrity of the joint. Such definiteness of diagnosis is seldom possible. An early diagnosis of the presence of disease can be made, but to determine the exact location of the primary focus is not possible.

Even operators of the most extensive experience, such as Volkmann, and George A. Wright have said that "if the case be taken in time the best results are obtained by rest." Mikulicz regularly treats his patients with joint tuberculosis by iodoform injection without incision. Considering all the evidence and giving due weight to the facts of experience, the writer is of the opinion that operative interference at the hip is seldom justifiable before the breaking down of tissue may be diagnosed.

The loss of the femoral head, whether through operation or the destructive process of disease, must be regarded as one of the most undesirable results. The shaft of the femur slides upward, and marked shortening occurs; but what is more serious, the end of the femur does not always secure firm anchorage, and when the weight of the body comes upon the limb the adjustment between the femur and the pelvis is found ill-suited to weight-bearing, so that the lack of fixation causes a very marked limp, the patient soon growing weary, and the pressure of the femur upward into tissues not designed to resist such intrusion causes pain. Sometimes the upper end of the femur finds an anchorage and much of the disability is thereby overcome. Shortening of

[1] Read at the thirteenth annual meeting of the American Orthopedic Association, held at New York, May 31, and June 1 and 2, 1899.

the limb, if it be less than two inches, need not in itself be considered a serious matter.

If the position here taken be admitted, that early operative intervention is not to be commended, then it is a most important question to determine what constitutes efficient mechanical treatment. Before attempting to answer this question it will be well to consider what are the elements which mark the successful result and what are the final conditions that constitute disability.

1. The most important is the subsidence of the disease, either through the efforts of Nature aided by art to completely eradicate it or at least to encapsulate the virus and imprison it so successfully as to prevent the manifestations of symptoms of its presence.

2. Motion is desirable if the head of the femur can be preserved and kept in the acetabulum; motion, however, is not the most desirable element in securing a successful result. Firm ankylosis, with the limb slightly abducted and fixed, is not a serious hindrance to the extensive use of the limb.

3. As some shortening is likely to result, a slight amount of abduction is desirable as the apparent shortening is thereby made less. Shortening of less than two inches does not in itself constitute serious disability as it is easily made up by a cork-soled boot.

4. If either disease or operative interference has destroyed the integrity of the joint a movable connection between the femur and the pelvis is a source of weakness and pain.

5. Adduction in any amount is always undesirable. Abduction to a greater amount than a few degrees is a cause of needless deformity. Flexion of more than fifteen or twenty degrees produces deformity and interferes with walking.

6. Atrophy of the limb is likely to cause life-long disability.

The mechanical treatment which implies that a patient shall be confined to bed cannot be considered an ideal treatment, as modern advances have conclusively shown that one of the most important considerations in all forms of tuberculosis is found in free exposure to fresh air and direct sunshine. The apparatus which shall be ideal must be a portable one to which the patient is definitely fixed. In the opinion of the writer, no apparatus hitherto described has been so successful and so completely meets the indications as the well-known Thomas hip-splint and its modifications. The posterior bar should be accurately adjusted. An ill-fitting splint is not only uncomfortable but fails to act efficiently as a mechanical appliance. Before the thoracic and pelvic bands and other parts are definitely attached it should be accurately molded to fit snugly to the body and limb of the patient. Care should be taken that sufficient bend is made at the knee to permit slight flexion. Following years of hip treatment by mechanical appliances it is not uncommon to find hyperextension of the knee and relaxation of its ligaments which causes considerable disability. This unfortunate result is as unnecessary as it is undesirable. In securing fixation of the limb to the splint it is not necessary to bandage the whole limb. Bandaging which confines the entire limb exsanguinates unduly and when long continued produces atrophy which is very detrimental to future efficiency. Similarly, the use of the ordinary adhesive plaster and its accompanying bandage is not to be commended. Extension by means of buckles sewn on the side of the boot, or a well-fitting gaiter, is better.

When the splint is employed simply to secure fixation alone it does not accomplish its best results. Traction is just as important as fixation. The constant tendency in the later stages is toward adduction of the limb and tilting of the pelvis upward on the affected side. If the splint be so constructed that traction can be conveniently made, drawing the limb downward while the pelvis is secured by straps producing counter-extension, not only is spasm of the muscles overcome, but the adduction which proves so pernicious may be prevented. In order to accomplish the latter purpose successfully, provision should be made for making the chief counter-extension on the sound side. A splint which produces counter-extension only on the side of the affected limb acts at a mechanical disadvantage and in spite of traction and fixation needless and injurious deformity is likely to result. If, however, through inattention to this matter there is considerable adduction, it may be better to place the patient in bed for a few weeks so as to overcome the deformity by traction produced by the aid of the weight and pulley. Afterward, however, this position can be maintained by the modified Thomas splint.

Traction which is made in the manner just described is effectual not only in preventing adduction and in overcoming muscular spasm, but it prevents needless attrition of the head of the femur against the acetabulum, and becomes a successful means of preventing actual and needless shortening.

A successful splint should thus enable us (1) to secure fixation for the joint, and (2) traction and abduction of the limb. In my earlier years I thought that a third purpose should be served, that a splint should be a crutch. Further observation has convinced me that the encouragement of this idea is likely to be detrimental. The effort to use

the splint as a crutch interferes with that completeness of rest from function of the diseased part which it is desirable to have in order to secure the best results.

A valuable and carefully prepared scientific paper was presented to this Association a few years ago by one of its members, and a conclusion reached adverse to the use of iodoform injections in the treatment of tubercular joint affections. It was a paper so carefully prepared, so full of detail, and so accurate in conclusion that I acknowledge myself greatly influenced by it. Notwithstanding that fact I am unable to withstand the weight of evidence that years of experience and observation have served to accumulate, that iodoform, however employed, when brought into contact with tubercular tissue is a most valuable adjunct to our means of treatment. The best results of my own experience in the use of this drug coincide very closely with those set forth by Dr. Henle of Breslau as the result of the work done in the Breslau clinic in the service of Dr. Mikulicz. Whether injected into the neighborhood of joints after incision and after evidence of the breaking down of tissue, or whether brought into contact with the tissue after excision made for the purpose of removing broken-down tissue, the writer has observed only the most favorable results and has reached the conclusion that it is one of the most valuable aids in treating tubercular joint disease.

The teaching of the last few years should not be forgotten or lightly passed over by the surgeon who is called upon to treat tubercular joints. Pulmonary tuberculosis is to-day considered amenable to treatment in a large percentage of cases. The most important points in securing efficient treatment in this domain are: (1) early diagnosis; (2) free and constant exposure to pure air; (3) as much direct sunshine as it is possible to obtain; (4) high altitudes and dry air; (5) good nutrition; (6) rest for the affected parts; (7) measures of prophylaxis. Not only in the sphere of medicine, but in that of surgery, evidence is accumulating to show more and more clearly that it is by attention to the general disease which is present that we must look for the best results.

If the amount of inflammatory product be more than Nature can successfully dispose of by absorption, and if the healthy tissue does not become successfully walled off from the diseased structures and the virus continues to extend the area of its noxious influence so that breaking down occurs, then the débris should be removed by operation, the surrounding tissue being wounded as little as possible, trusting largely to natural processes aided by drainage, cleanliness in nursing, good diet, abundant fresh air, plentiful exposure to direct sunlight and rest for the part to put a stop to the further ravages of the disease and to secure cicatrization.

Of the cases of hip-disease that have come directly under my care during ten years, and which have been in the main treated in accordance with the teaching of this paper, I have been able to trace and obtain fairly reliable records in 70 cases. Of this number 9 patients are dead. One, a boy of sixteen, had Pott's disease and hip-disease and died of general tuberculosis; one, a girl of fourteen, had Pott's disease and hip disease and died of general tuberculosis; one, a girl of fifteen, had discharging sinuses for a long time and died of amyloid disease; one, a girl of fourteen, had pulmonary tuberculosis with cavities when first seen; one man, aged thirty-four years, died two years after recovery. I have not been able to obtain a reliable account of his last illness, but believe it to have been tubercular meningitis. One boy of fifteen died of typhoid fever two years after recovery from hip-disease; one boy of eight died of tubercular meningitis, though for several months previously he seemed to be convalescing satisfactorily. One girl of sixteen had general tuberculosis with dropsy: one girl of fourteen died a few days ago of tubercular meningitis. This patient had come under my care early in the course of the disease and had seemed to make the most gratifying progress toward recovery until about two weeks ago when her fatal illness appeared. With the exception of the last patient all had suppurated abundantly and six of the number had manifested signs of the disease for a long time without having any efficient treatment.

In 36 of the 70 cases suppuration occurred. Of these, 21 patients made a good recovery according to the standard of good recovery set up in this paper. Of these, 3 have recovered without a limp in walking. Of the whole number of patients 5 have recovered without limp and 5 others have but a slight limp. The oldest patient was fifty eight years of age, and 7 were more than twenty years of age, 2 being about forty, and 2 more than fifty.

Permit me briefly to summarize:

1. Hip-disease is a local manifestation of a constitutional disease.

2. Early operative treatment is seldom justifiable.

3. When softening can be determined the surgeon should operate and obey indications, observing all care not to needlessly injure the mechanical integrity of the joint.

4. In the subsequent management of the wound asepticism and antisepticism must be carefully observed.

5. From the earliest moment efficient protection for the joint should be secured and constantly maintained by a well-fitting mechanical appliance.

6. A proper splint should fulfil two indications, *i.e.*, secure rest for the affected joint and prevent deformity. No effort should be made to employ the splint as a crutch; ordinary crutches should be used. In the adjustment of the splint the knee should be slightly flexed.

7. Constitutional treatment is indicated as in other tubercular affections. Great emphasis should be laid on obtaining the freest exposure to direct sunshine and fresh air. Free use of iodoform is a valuable adjunct.

8. After excision a perfect recovery never follows because the mechanical integrity of the joint is not preserved.

9. Following mechanical and constitutional treatment complete restoration of function is sometimes obtained.

10. Even when breaking down of tissue occurs which necessitates incision there is sometimes a perfect restoration and frequently a highly useful return of the joint function.

VAGINAL COLPOTOMY IN THE TREATMENT OF PELVIC DISEASE.[1]

By JAMES H. GLASS, M.D.,
of Utica, N. Y.;
Surgeon in Charge of Faxton Hospital.

When Langenbeck, early in the present century, removed methodically and successfully the carcinomatous uterus through the vaginal canal the scientific and surgical treatment of pelvic disease through the vagina was inaugurated. Not until the memorable discussion which occurred in the Paris Surgical Society in 1888 and was participated in by Pean, Terrier, Richelot, Verneuil, Bouilly, and Segond did vaginal section, however, receive the impetus which resulted in placing it among the recognized and accomplished surgical procedures. To the efforts of Pean and the French school, supplemented by their painstaking and methodical brothers, the German surgeons, is due the credit of the perfected technic of modern vaginal hysterectomy, an operation which in certain selected cases is deservedly popular, threatening at one time to become the fashion. Emmet, in his vaginal puncture and drainage, suggested, while Landau abroad and Henrotin in this country, perfected and popularized the modern vaginal section for pelvic suppuration. The present tendency is to a greater conservatism in the employment of vaginal section, a method which (always having in mind its special adaptability) will no doubt shortly take a stable and ascertained place as a legitimate and valuable surgical procedure.

The range of usefulness of vaginal section in the treatment of pelvic disease while large is by no means unrestricted and, notwithstanding as a method it has advanced so rapidly in favor with the best and most conscientious of our profession, we cannot be too critical in our estimate or too general in our discussion of a comparatively new operation, however apparently good, as by these means possible errors or premature conclusions are eliminated and permanency of position for the procedure procured. The revolution of opinion as to the value of vaginal section in the treatment of pelvic abscess might well be illustrated by the recitation of a personal experience of the writer eight years ago, in which the life of a patient was lost, not as a result of the operation, which was extremely simple, but as the result of its incompleteness, subsequent examination showing that the entire pus-producing tract was not drained, or what is more probable, that infected or involved areas breaking down after operation were not drained. A subsequent consultation with two distinguished gynecologists, who at the present time are generally recognized as special exponents of the vaginal method of operation in New York and Chicago, respectively, while securing for the operator a justification of the procedure, was faint in its endorsement of the method employed. This case at once illustrates one of the chief disadvantages of vaginal section in pus cases, *viz.*, our inability to judge always of the completeness of the procedure, therefore, the possibility of leaving undrained pus accumulations in multilocular abscesses or suppurating multilocular cysts. Admitting the force of this objection, the disadvantage of the tactile sense as a guide in these operations, and noncurative effects in a certain number, there yet remains an enormous balance in favor of vaginal operation, than which none has yielded the brilliant results obtained by incision and drainage of large infective or pus accumulations in the tubes, interligamentary spaces, cellular tissue, or peritoneum. Whether the collection be the result of gonorrheal or post-partum infection, ectopic gestation (provided active hemorrhage is not going on), or what not, the indication here is the same as obtains in dealing with pus collections in the practice of general surgery, to drain, and the simplest and most efficient means of accomplishing the object is that which most commends itself.

That the vaginal operator does this would seem easy of demonstration, and the operation is easier done.

[1] Read before the Jefferson County (N. Y.) Medical Society, April 11, 1899.

There is no doubt that the vaginal as compared with the suprapubic operator is frequently called upon to exercise greater nicety of judgment and manipulative dexterity, as normal anatomical relations are more disturbed by the traction sometimes necessary in vaginal operations, and excepting in those cases in which circumstances demand immediate intervention, the operator should be fully competent and prepared to do a suprapubic section should hemorrhage or other unforseen condition present to interfere with the completion of the operation through the vagina. The fact remains, however, that the average vaginal incision for pus is a comparatively simple one. The tyro might with impunity and propriety, as a temporizing measure or in an emergency, incise an extraperitoneal pelvic abscess through the vagina, whose intervention with the same condition through the suprapubic incision would be considered little less than homicidal. Through the vagina the abscess is incised at its base. Observation teaches that in most pyosalpinx cases the abscess breaks, if at at all, when separating adhesions in its lower posterior aspect, a most unfavorable situation to deal with in suprapubic celiotomy, yet the most advantageous point possible when the sac is attacked from below. Drainage is dependent and the septic discharge is through tissues whose absorbents are plugged by inflammatory exudate or protected by auto-antitoxic products. The danger of further infection is thus reduced to a minimum, a consideration of vital importance when contemplating the hazard of infection incidental to the up-hill capillary abdominal drainage through long, clean tracts of peritoneum and muscular and connective tissue. Operations of this class are usually completed without invading the peritoneum. They are possible in the desperately sick, subjects in whom suprapubic section would not be admissible or necessarily fatal at the time, and who, if necessary, may be submitted to more radical or complete surgical methods at some subsequent time. The mortality is greatly reduced, falling as it does in these cases below five per cent., a marked contrast to the mortality in the suprapubic operation, which may be conservatively estimated at about twenty per cent. in the work of our representative gynecologists. Four times within the past three months the writer has been able to save life through vaginal section and drainage of large septic collections in cases in which by reason of the extreme sepsis and exhaustion suprapubic section must have resulted disastrously.

In the consideration of the preparation of the patient for vaginal section the recent bacteriologic investigations made for the purpose of demonstrating the natural aseptic or antiseptic quality of the genito urinary tract of the female should be excluded or ignored, in view of the fact that about all the patients coming under observation have such departures from normal conditions as to make such propositions untenable. Therefore it is desirable, if possible, to prepare the patient a day or two prior to operation by thoroughly scrubbing the vagina and adjacent parts with green soap and water, frequently irrigating meantime with antiseptic solutions, mercuric bichlorid or lysol, preferably, because of their active destructive effect on germ-life. The final sterilization may be left to the operator or assistant after the patient is brought to the operating table and the anesthetic given, when, with the patient in the dorsal position, the preliminary curettage is done, the uterine cavity thoroughly irrigated, perhaps cauterized and packed with antiseptic gauze, the vagina again thoroughly scrubbed with soap and water and freely douched with antiseptic solution, the parts are ready for invasion.

The technic of vaginal section should be varied to meet the special indications in a given case. The fact that one operator meets these indications in the greatest number of tubal troubles by an incision into the vesico uterine space, or begins his incision here for vaginal hysterectomy, and controls hemorrhage by the use of clamps; and that another controls the situation presenting to the best advantage by cautery incision or otherwise into the posterior cul-de-sac, or prolongs it from this point, ligating the bleeding vessels instead, is no argument against the technic of yet another, who so modifies his incision and hemostasis as to accomplish the object in view with the greatest ease and simplicity.

As a general proposition we believe that vessels should be isolated and ligated as much as possible as the steps of the operation are taken. By this means we are assured a process of tissue atrophy rather than slough, reducing to a minimum the danger of secondary hemorrhage from separation of slough or disarrangement of clamps or the occlusion of the ureters and the prolonged fetid septic discharge, either of which conditions may obtain as the result of crushing considerable amounts of tissue *en masse*.

The performance of the operation of vaginal section is simple. Seizing the cervix with a Colin or other traction forceps, having due regard for the rectum, bladder, uterus, and larger vessels, the vagina is made tense and incised well outside its reflection on the cervix and nearest the point of election, whether in the anterior or posterior fornix. Dissection with the finger is continued until the pus collection is reached, when a blunt scissors or for-

ceps is pushed well inside the abscess cavity, opened to the width desired, and withdrawn. With the finger clots, exudates, exfolia, or necrotic masses are removed and the cavity is wiped with antiseptic compresses, not washed out (as by so doing septic material might find its way through a possible opening in the peritoneum), after which the cavity is lightly packed with gauze, or a tube wound with gauze introduced, the latter method securing better drainage and patency of the opening.

An amplification of these incisions laterally through the posterior cul-de-sac or longitudinally along the roof of the vagina in front, always having in mind possible injury to the ureters or bladder, affords a good opportunity for an intraperitoneal examination of the tubes and ovaries, which may be relieved of adhesions, drawn down and inspected, and replaced if healthy, or resected or excised if diseased; serous and septic accumulations in the adnexa, if too large to deliver through the opening, may be tapped and excised. Pedunculated myomata of small size may be ligated and excised, or if sessile, enucleated, the peritoneum being replaced and sutured in position. A study of the advantages of this method of management will, we believe, materially diminish the indications for suprapubic hysterosalpingo-oophrectomy, and other mutilating operations upon the abdominal wall, uterus, and adnexa.

Combined operations involving the vaginal vault, of the sacral and par-sacral order, present special dangers in the liability of injury to the ureters, rectal fistula, shock, and sepsis, not compensated for by the advantages obtained or required except in cases of advanced cancer, which are as a rule unsuited for any operation. A method of rectal excision through the vagina for cancer is described and warmly advocated by Gersuny, Moeller, and Rehn. The sphincter is incised and reunited, affording, it is said, a most excellent exposure of the operative field. Like most other operations proposed for excision of the rectum the immediate results are satisfactory, but the ultimate outcome is disappointing. Any procedure, however, which offers a simplification of method in operations for malignant rectal disease is entitled to the most serious and careful consideration.

In advocating the propriety of employing the vaginal route, and the operations which naturally follow for fixation or suspension of the prolapsed or retroverted uterus, we are conscious of opening up a broad subject. There is little opportunity, however, for contention on the part of the advocates of suprapubic operations in these cases, as the same objection —dystocia—obtains in a certain percentage of all. Any operation having for its object the rectification of a uterine displacement must be, in some respects, unsatisfactory, as it cannot be anatomical. In an examination of the literature of the subject from the time when Dührssen and Mackenrodt first published their method of vaginal fixation of the uterus it is apparent that practically all of the unfavorable results reported in the many modifications proposed are in cases in which abdominal or vaginal fixations, as distinguished from suspension operations, have been done. It is fair to assume that the difficulties attending parturition after either operation have been exaggerated and that we are justified in expecting a spontaneous and uncomplicated delivery in such patients as have been operated upon after the later method of Wertheim, or some one of its modifications. Whether the round ligaments have their slack taken up by an approximation of the ligaments of both sides, or are shortened by taking up or cutting out a loop is of minor importance, so that their supportive quality is retained and their functions restored. The method of Wertheim is as follows: The vesico-uterine pouch is incised in the usual manner. The uterus is anteverted, the fundus made to present at the opening (perimetric, intestinal, and omental adhesions being divided, if necessary, with the Paquelin cautery, as advised by Dührssen and Kustner), the round ligament on each side is exposed, a loop one inch from its origin on each side is brought into the field of operation and sutured to the outer angle of the vesico-uterine fold of the peritoneum, or the corresponding angles of the vaginal wound if greater permanency is desired. The peritoneum and vagina are closed separately, the fixation sutures, if through the vaginal wall and unabsorbable, being removed after six weeks. Vineberg, who described this operation independently, with others, has reported uneventful parturitions after its performance. The immediate effects are good, the same elevation and anteversion being procured as after the Adams-Alexander procedure. The usual dislocation of the bladder is absent as the fundus does not rest upon that organ. As compared with the Alexander operation, there is no external scar, the ligaments are easily recognized and found at their origin, having sufficient resistance at this point to stand the strain imposed. It is claimed that greater manual skill is essential to the easy performance of the operation, an assertion to which we are loth to agree after having on several occasions witnessed the confusion of most dextrous and experienced operators who failed to find the round ligaments in the Alexander operation, or finding the ligaments, breaking them in handling because of extreme friability. The perfected vaginal suspension of Dührssen we regard incomparably superior to

ventrofixation or suspension, unless the latter be employed to meet special indications as adhesions, narrow vaginæ, etc., or incidentally in conjunction with other operations through the abdominal wall, and it seems to us abdominal section for the purpose only of suspensio-uteri is unwarrantable.

In a consideration of the question of hysterectomy for malignant disease, the importance of early diagnosis cannot be too much emphasized. If the uterus is freely movable, even though there be some involvement of the vaginal wall, good results are not impossible. If, however, the disease has extended well into the ligaments and the uterus is fixed, operation is contraindicated. There is a growing tendency in this country and abroad to the employment (especially in advanced cases, or those in which the corpus uteri is involved,) of the more radical vagino-abdominal operation of Clark of Johns Hopkins Hospital or Polk of New York. Clark's method is that of preliminary catheterization of the ureters and ligation of the uterine arteries at their origin, enabling the operator to cut the broad ligaments much shorter, at the same time removing the iliac and retroperitoneal glands which may be infected in these cases. The proposition of Polk for hemorrhagic control is even more radical, as he advocates the ligation of the anterior trunk of the internal iliac arteries. By this means a comparatively bloodless field of the floor of the pelvis and posterior vagina is secured, admitting of the more ready recognition and protection of the ureters at their entrance into the bladder, while facilitating the removal of all infective tissues, including the iliac, uterosacral, and retroperitoneal glands. The technical objections to these operations, however, are such (Clark, for example, stating that his operation consumes 2½ hours of time) that the average surgeon will be very loth to supplant the modern vaginal hysterectomy with its rapid execution, slight shock, freedom from restraint, quick recovery, and low mortality, with the tedious procedure proposed except in cases of advanced disease. Notwithstanding the great diversity of opinion among medical men, as to the disposition of malignant disease of the uterus to recur, the pathologic fact remains, as Winter has shown and Russell substantiated, that cancer of the cervix exhibits an inherent tendency to remain localized. Its indisposition to metastasis is shown by Russell, who in a study of the cases at Johns Hopkins Hospital, found that in all the cases of recurrence the growth was entirely local. A still more significant fact is that the records of ten inoperable cases at Johns Hopkins Hospital show that in only one instance was there involvement beyond the pelvis, or of the retroperitoneal glands. In his address before the German Congress of Surgery, Olshausen reviewed vaginal hysterectomy, its improvements in technic, and its results, showing that German statistics indicate such improvement in permanent results that it is now possible to assert that "there is hardly an organ in the body in which operations for the cure of cancer can be performed with such confident expectation of permanent good result as in the uterus."

The steps of the operation may be modified to suit the particular indications of the case. The patient, in the dorsal position, is brought to the edge of the table the legs supported by rests or assistants, and the posterior vaginal wall retracted with a Simon speculum, exposing the vault of the vagina and cervix, which last should be curetted, cauterized and packed or closed with three or four sutures, which may be used as the operation progresses as stays or guys in fixing the uterus; or the cervical canal may be clamped close with a strong Colin traction forceps with which the uterus is strongly drawn down to the vaginal outlet. The posterior cul-de-sac is then incised as far down on the cervix as admissible. Should the hemorrhage be free it is controlled at this point by a deeply set ligature placed in either angle, after which the incision is continued around the circumference of the cervix, the extent and density of which in different cases varies greatly. The cellular tissue is now pushed back with the finger from its attachment in front until the bladder is detached, which with the ureters, is carried well up out of harm's way. The rectum is further detached by the same stripping process up to the origin of the broad ligaments where the uterine arteries and their branches are caught up, tied, and cut away. With a volsellum forceps the fundus is now rotated forward, the tubes and ovaries on each side delivered, ligated, and excised, unless it should be deemed feasible to leave one ovary for its effect on general nutrition. The broad ligaments are then approximated with the anterior and posterior folds of the peritoneum with buried catgut suture, and the vaginal orifice closed in a similar manner, or antiseptic gauze is tucked lightly into the wound and left for several days, after which daily irrigation is sufficient to secure good reparative conditions. This general method may be applied to hysterectomy for uterine fibroma. Many operators, however, prefer to bisect the uterus in the course of its removal, a method of apparent advantage in the case of large growths.

The advantages claimed for vaginal as against abdominal section may be summarized as follows: (1) A preliminary or exploratory vaginal section is always warrantable. (2) Drainage when necessary is

more free and natural. (3) There is less danger of extending infection. (4) The limited peritoneal field exposed and handled reduces to a minimum pain, shock, and intestinal paralysis, frequent sequelæ of suprapubic abdominal section. (5) Post-operative nausea is lessened and movements of the patient are less constrained, contributing much to her comfort and general welfare. (6) Vaginal section may frequently be performed when the condition of the patient, especially in abscess cases, would interdict any other precedure. (7) The danger of hernia through the scar is practically *nil*. (8) Recovery is quicker. (9) The mortality, as calculated from all reported cases, is materially lessened.

The contraindications for the vaginal operation are: (1) An unusually small or septic vagina. (2) Such fixation of the uterus that it cannot be drawn down, or such enlargement of the organ that operations on the adnexa, when desired, cannot be carried out. (3) Evidences of tubercular degeneration or appendicular disease. (4) Carcinoma with involvement of the uterine ligaments or iliac glands. (5) Cases of pelvic hematocele with active non-circumscribed hemorrhage.

THE TREATMENT OF INCIPIENT LARYNGEAL CANCER.

By W. SCHEPPEGRELL, M.D.,
OF NEW ORLEANS, LA.

There is no subject in laryngology which is of greater importance than the treatment of incipient laryngeal cancer. As in other forms of malignant disease, the hope of success is in the inverse ratio of its duration. It is only in the early stages that a hope of a cure presents much encouragement, not only on account of the more favorable prognosis, but also because we can at that time avoid those radical operations which, while extirpating the disease, have so high a mortality and mutilate the patient to such a degree as to have made their justifiability a question of discussion. The treatment of malignant diseases of the larynx in general has received considerable attention in recent years, and great advances have undoubtedly been made in this respect. The classes of malignant tumors and their relative treatment have also been systematized, which materially assists in the scientific treatment of this formidable condition.

Whatever method be selected, the total eradication of all the diseased area presents the only hope of success. As this result can be best effected in the incipiency of the disease, surgical interference at this time is of the utmost importance. An operation, however, is dependent upon an early and correct diagnosis, but this unfortunately is frequently quite difficult in the incipiency of the disease. The majority of investigators admit the difficulty which frequently arises in making a correct histologic examination in these cases. The differential diagnosis between papilloma, pachydermia, tuberculosis, and syphilis, while easy in typical cases, often presents the gravest difficulty. The discussion of this subject before the recent meetings of the various laryngologic and surgical associations leaves no doubt that there is considerable room for improvement in this direction.

Another source of danger is that cancer may be localized for a considerable time in this region without giving rise to symptoms sufficiently urgent to compel the patient to seek medical advice. In many cases slight hoarseness is the only symptom present for many weeks. This shows the importance of using the laryngoscope in such cases, as persistent hoarseness in persons of advanced age should always be regarded with suspicion and carefully investigated.

The study of the treatment of malignant disease of the larynx has been greatly facilitated by a number of recent writers who have carefully investigated this subject. Among these are Mr. Watson Cheyne, who published the Lettsomian lectures: Drs. Sendziak of Warsaw, Bryson Delavan of New York, Sir Felix Semon, M.D., and Mr. Butlin, of London; Drs. Schmiegelow of Copenhagen, Kocher of Berne, and O. Chiari of Vienna.

Among the non-operative methods of treatment may be mentioned that by the animal toxins, which has recently received considerable attention, the local use of arsenious acid, pyoktanin, etc. The animal toxins appear to have had what little success is attributed to them in cases of sarcomatous tumors, while even those who show the greatest enthusiasm for this form of treatment claim little, if any, benefit from its use in epithelioma. The toxins which have been found of the greatest value are the streptococcus erysipelatosus and the mixed toxins of streptococcus erysipelatosus and bacillus prodigiosus. Some degree of success has also been obtained from the injection of a solution of arsenious acid, one case of apparent cure having recently been reported by Costinin.[1] Pyoktanin has also been recommended in these cases.

In malignant diseases, the important consideration is the entire eradication of the diseased area, and the above methods of treatment are applicable only in the cases in which for any reason an operation is contraindicated. In such cases they may be used as a palliative measure, as a hope of cure is admitted to be extremely small.

Regarding operative measures, there have been many discussions as to the relative value of the endo-

laryngeal and external operations. In advanced cases there can be but little doubt of the necessity of one of the forms of external operation. In incipient laryngeal cancer, however, which is the subject of this article, the question of endolaryngeal operations demands earnest consideration, as a number of successful operations have been reported by careful observers. Juraz of Heidelberg[2] reports a successful outcome in a case of epithelioma which developed on the right vocal cord, an interesting feature of this case being that it produced by contact a similar change in the symmetrical part of the left vocal cord, thus giving an instance of what has been described by Semon and Butlin as "auto-inoculation" of cancer. In cases in which the disease is circumscribed, as in the polypoid form, especially if limited to the vocal cords, the endolaryngeal operation should be given a trial. It is strongly contraindicated, however, in the diffused form. In many cases it is extremely difficult to fix the limits of malignant disease and, where there is any doubt, an external operation in which the part can be carefully inspected should be undertaken.

The endolaryngeal operation should be performed with forceps, double curettes, or the cold snare. The electrocautery, electrolysis, and cataphoresis should not be used in incipient cases, their application being limited as a palliative measure when complete extirpation is not practicable. The endolaryngeal operation is favored in suitable cases by Schmiegelow,[3] and Chiari[4] has shown that laryngeal cancer is capable of cure in many cases and that therapeutic nihilism is here altogether out of place. One of the greatest champions of this method is Fraenkel,[5] who recently reported a series of nine cases, five of the patients being cured. Sendziak has collated thirty-two reports of cases of endolaryngeal operation in which complete cure was proven in 12½ per cent. three years after the operation. The majority of operators, it must be admitted, have not been so successful, and Semon and others claim that permanent success is rare.

As the prognosis of cure is far greater when the disease is taken in its incipiency, the operation should be performed as soon as a diagnosis of cancer is made, while complete removal of the diseased tissue is possible and the patient strong enough for so serious a procedure. As long as the malignant growth is situated within the cartilaginous structure, the prognosis is much more favorable than when it has reached beyond these limits. When the diseased process attacks the epiglottis, aryepiglottic folds, or arytenoid cartilages, hope of success is far less because of the early implication of the lymphatic glands; but even then cure has been obtained.

Thyrotomy is considered the rational method of treatment for laryngeal cancer by many operators. It has the advantage of giving a clear view of the diseased area and enables its extirpation to be scientifically undertaken. The subject of tracheotomy, as associated with thyrotomy, has received considerable attention, especially as regards the interval between the two operations. As a palliative measure in advanced cases, when the respiratory passage has been occluded by the growth and when a radical operation is contraindicated, it is necessary to establish an artificial opening for respiration, and tracheotomy is required. Intubation, although undertaken in rare instances, is not advisable in these cases. Some operators perform the preliminary tracheotomy and the radical operation during the same anesthesia, but many prefer an interval between the two, so as to avoid the shock of the double operation and to prevent many of the inconveniences arising from the tendency to hemorrhage after tracheotomy; it has also the advantage of accustoming the patient to this artificial method of breathing. I have made it a rule in my practice to leave an interval of a week between the two unless the indications for a radical operation are extremely urgent.

The external operation has been subdivided into various forms, such as thyrotomy, pharyngotomia subhyoidia and lateralis, pharyngotomia transversalis, partial resection, and total laryngectomy. Chiari has described these in detail and gives the special indication for each operation. Thyrotomy is the most universally recommended, but pharyngotomia subhyoidia is indicated when the neoplasm is situated either on the epiglottis or aryepiglottic folds; pharyngotomia lateralis when the epiglottis or arytenoid cartilage is involved. Pharyngotomia transversalis is recommended by Gersuny as giving the operator a more complete view of the interior of the larynx, but it is rarely practised.

In the case of a tumor of the larynx suspected of malignancy, Delavan[6] believes that not only should thyrotomy be performed for its extirpation, but that it is entirely justifiable to make an exploratory thyrotomy.

Total extirpation of the larynx is a radical operation which was first recommended by Billroth, in 1873, and has since been successfully performed in a number of cases. This operation is not to be recommended, however, for incipient cancer of the larynx. Laryngectomy may be partial or complete, and may or may not include the neighboring glands, according to whether these are involved or otherwise. The case of J. Solis-Cohen[7] is well known, not only on account of its success, but also because the patient developed an intelligible form of speech

after the total extirpation of the larynx. Several similar cases have recently been reported. The advantage claimed for this operation is that the ends of the trachea are brought to the external edges of the cervical incision and there retained, thus cutting off communication between the larynx and the lungs and diminishing the danger of Schluck-pneumonia, and facilitating the act of swallowing.

As regards the danger of total laryngectomy, Sendziak has collated reports of 188 cases of extirpation with a mortality of 84 per cent. The technic of the operation has, however, been improved in recent years so that the prognosis is now somewhat more favorable. When the malignant disease has advanced to such an extent as to require the complete extirpation of the larynx for its removal the prognosis is not only very unfavorable but many operators have even doubted its justifiability on account of its attending danger, high mortality, and the mutilated condition of the patient after the operation.

CLINICAL MEMORANDUM.

REPORT OF TEN CASES OF EPIDEMIC CEREBROSPINAL MENINGITIS.

By E. B. DOOLITTLE, M.D.,
OF HAZLETON, PA.

THE following cases seem worthy of report, chiefly on account of their strong relationship clinically and etiologically to acute lobar pneumonia. Unfortunately as no autopsy or bacteriologic examination was made in any case no positive deductions can be drawn.

These ten cases of cerebrospinal meningitis occurred during the winter and spring of 1899, in Jeanesville, Pa., a small village of about 800 inhabitants, while adjoining and far more populous towns were entirely free from it.

One case occurred in November, one in February, and the remaining eight between March 11th and May 18th, four being in April and two each in March and May.

Sex.—Six of the patients were males and four females.

Age.—Three of the patients were between eighteen and twenty-eight years of age, and seven were between four and eleven. In no instance did two cases occur in the same family, though five cases occurred in families living within a distance of two blocks all in one street.

General Conditions and Hygiene.—All of the patients were previously in good health. At least one-half would be classed as vigorous and robust. Eight of the cases occurred in families who were well-to-do and whose hygienic surroundings were the most favorable in the town. None was in decidedly bad sanitary surroundings.

Fatality.—Five cases or fifty per cent. were fatal.

Types.—No case of the fulminant or abortive type occurred in the series. The duration in fatal cases varied from four to twelve days; average about seven days. The duration in the case of patients who recovered varied from two to seven weeks; average about four weeks.

Onset.—The onset was sudden in nine cases. In one case it was more gradual. Headache, gradually increasing, existed for two or three days previous to the attack. Four cases were ushered in with a chill, vomiting, headache, fever and pain in the chest. (These patients all developed acute lobar pneumonia.) The remaining five cases began with vomiting, headache, fever and pain in the side, usually the right. The pulse was elevated in all, usually to about 120. The respirations were increased, varying from 30 to 60. The temperature was irregular, usually above 102° F. at onset and often 104°, later reaching 106° in some of the complicated cases.

Vomiting was present early in every case. Pain in the side, most frequently the right, and headache was present in every case. Pain in the abdomen was noted in four cases. Photophobia, more or less marked, was present in all the cases. The pupils were usually contracted slightly but reacted, though irregularly. Delirium, usually mild in type, was present in every case early and usually continued until convalescence was well advanced. Coma, slight in the milder cases, profound in the fatal ones, existed in all. Tenderness over the cervical region with beginning spinal rigidity was rarely ever present until the third and sometimes the fourth day of the disease but was present in every case. General hyperesthesia was present in five cases. Muscular twitchings were observed in most of the cases. No paralyses were observed in the case of any patient that recovered. Flexion of the leg upon the thigh and the thigh upon the body was often present in children.

Eruptions.—Herpes-labialis, usually the upper lip alone being affected, was present in every case, appearing from the second to the fourth day, and was the only eruption observed.

Complications.—Pneumonia, single or double lobar in type, was a complication of four cases from the beginning. All were fatal. Slight cough, with a very scanty slightly blood-stained expectoration was present in every case before the third day. Albumin was present in the urine in every case. No casts were found. Involvement of the joints was noted in two cases, consisting of swelling, pain, and tenderness. Of the patients that recovered none suffered from the impairment of any organ or function. One had a slight attack of purpura of the lower extremities about three weeks after recovery.

Diagnosis.—The fully developed disease presents no difficulty in diagnosis; but in the early stages, before the cervical tenderness and muscular rigidity occur, which in this series of cases was not until the third day, it is by no means so easy to distinguish it from pneumonia, more especially as all of these cases were ushered in by symptoms usually present in pneumonia. Vomiting, which is almost constantly present in meningitis early in the dis-

ease and rarely in uncomplicated pneumonia, together with the early appearance of consolidation of the lung in the latter and its absence in meningitis, appear to me to be the most prominent features distinguishing the two diseases in the early stages.

It may be worthy of note that during the month of April, in which month the largest number of cases occurred, ten cases of acute lobar pneumonia also developed in the same locality, more cases than had previously occurred in the neighborhood for more than a year. We are led to believe from clinical observations that in some epidemics at least cerebrospinal meningitis in its etiology is closely allied to acute lobar pneumonia.

MEDICAL PROGRESS.

Modification of Plastic Operations on the Lips.—SILBERBERG (*Centralbl. f. Chir.*, May 27, 1899) suggests a modification in the technic of operating for cancer of the lips, which shall give a complete red edge to both lips. It is only possible when the angle of the mouth is not excised. For instance, after the usual V-shaped excision of a growth in the lower lip, a double-edged knife is passed through the upper lip, at a little less than an inch from the angle of the mouth. The blade is passed obliquely so that the mucous surface shall be wide. The incision is made along the red border to the angle of the mouth, and then on out into the cheek for an inch or more, and thence downward toward the point of the chin in a line parallel to the edge of the V-shaped wound made by removal of the growth. Such a cut is made in both cheeks, and when the gap in the lower lip is closed by bringing together these flaps from both cheeks the angles of the mouth will be shifted from their usual positions to the points in the upper lips where the incisions began. The two lips being thus made of equal length, deformity of the mouth is avoided. This principle of operation can be adapted to any of the incisions about the mouth, which leave its angles intact.

To Heal Vaccination Sores.—BOND (*Maryland Med. Jour.*, July 1, 1899) says that although the most careful vaccination with fluid lymph will sometimes be followed by an ugly sore, the impression that one must wait with patience, as the sore will not heal for several weeks, is entirely unfounded. In all such cases the application, after removal of the suppurating crust, of a solution of nitrate of silver of 80 grains to the ounce will cause the sore to dry up, so that it may heal after one dressing. If the protective cotton again soaks through with pus in the course of a week, the treatment is repeated over the much smaller area, and this application will complete the healing. A solid silver stick will answer as well, but it causes much pain, so that children dread a second application, while the eighty-grain solution is almost without pain. By pursuing this line of treatment the annoyance of an arm which shall be sore for months, perhaps, is done away with and one of the strongest objections to vaccination is thereby overcome.

Syphilis and Tabes Dorsalis.—KUHN (*Centralbl. f. inner Med.*, May 27, 1899) attempted to gain some further knowledge of the relation between syphilis and tabes by looking into the history of some 800 hospital patients under treatment for nervous diseases. Some 214 of them had tabes. He found that a syphilitic history was five times more common among the tabetic than among the non-tabetic patients. Considering the large number of patients examined, this great difference cannot be set down as an accident, and while unwilling to go as far as Erb, and declare syphilis to be the chief, if not the only, cause of tabes, the author thinks that all must admit that it is one of its important antecedents.

Excision of Inflamed Bursæ in the Popliteal Space.—HAWKES (*Ann. of Surg.*, July, 1899) describes the successful excision in four patients of the inflamed gastrocnemio-semimembranosa bursa. This bursa, which as its name indicates, lies in the inner part of the popliteal space between the inner head of the gastrocnemius and the tendon of the semimembranosus muscles is one of the constant bursæ about the knee-joint. In about one-third of the cases examined it has been found to communicate directly with the knee-joint. In some instances there seemed to have been a traumatic cause for the bursitis, such as a sudden straining of the muscles but in others no cause for the swelling could be learned. The chronic swelling gives rise to little pain, but causes a weakness and full feeling of the knee, which if allowed to increase may interfere considerably with the function of the limb. The condition must be differentiated from aneurism, lipoma, cold abscess, sarcoma, and from inflammation in some other bursa of the region. No cures have been recorded from internal medication, nor from outward applications nor compression. Aspiration of the contents is difficult on account of the thick character of the fluid and is dangerous as several cases have been recorded in which purulent inflammation of the knee-joint followed, and amputation of the limb was necessary to save life. Nothing better can be said of the injection of carbolic acid, iodin, etc. Excision is the treatment of choice, and after the limb has been rendered bloodless by an Esmarch bandage, it is carried out without difficulty. Hawkes obtained primary union in the case of all four of his patients. After operation the limb was held fixed for two weeks by a plaster-of-Paris bandage.

Suppurative Phlebitis and Lymphangitis of the Pelvis after Childbirth.—THOMAS (*Centralbl. f. Gyn.*, June 17, 1899) says that if the history of the illness is supplemented by a careful physical examination of the patient it is possible to make a differential diagnosis between suppurative phlebitis and lymphangitis of the pelvic organs during the puerperal period. Lymphangitis spreads gradually in the planes of the connective tissue; phlebitis makes a discrete swelling in the region of the large veins, outside of the ligaments, and shows no tendency to spread but rather to remain the same for weeks. The posterior and anterior peritoneal pouches tend to remain free, while in lymphangitis they are especially involved. If suppurative phlebitis spreads it does so by metastasis while the patient

suffers from chills. It is rare that a patient having lymphangitis dies from a rapidly advancing septicemia. The usual course of the disease is to become localized in the broad ligament of one side, or to disappear altogether. When a fever appears during convalescence from childbirth, one should not hastily brand it as milk-fever, or as due to metritis until the uterus is examined. Often there will be found circumscribed swellings at the points where the large lymph-vessels leave the uterus, swellings which will disappear without any special medication if the patient is kept quiet and is given a suitable diet and the bowels are kept free.

Surgical Treatment of Incontinence of Urine in the Female—FLOUQUET (*Jour. des Sci. Med. de Lille*, May 20, 1899) describes a new method of treatment of incontinence of urine in women. The plans previously proposed have been expected to accomplish their object by constriction of the urethra or deviation of its canal. Schultze resected an oval piece of the urethra from the neck of the bladder to within half an inch of the meatus. The wound was closed with seven or eight sutures. Edgstroem performed the same operation, but avoided the mucous membrane, because if the suture did not hold, the vaginal fistula made the condition of the patient far worse than before. Franck modified Schultze's operation by taking out two lateral ellipses and suturing in such a manner that the central portion of the mucous membrane was crowded into the lumen of the urethra, like a hypertrophied third prostatic lobe. Desnos tried to constrict the posterior portion of the urethra by passing a thread around it, but the results were inappreciable.

In 1880 Pawlik began a series of attempts to cure incontinence by approximating the walls of the urethra, and changing the direction of its lumen. Anterior operations were found to give rise to fistula. Guersuny planned to twist the urethra on its long axis, and by increasing the resistance to the flow of water, prevent incontinence. These two plans have been altered and combined by different operators, and in some instances with considerable success. Blech tried to increase the pressure on the external meatus, by making a vertical incision in the skin on either side of it, and suturing the wounds transversely. This operation can be performed under cocain, and can not well make the condition of the patient worse even if it fails to accomplish its object. Albarran reported the cure of incontinence by separation of adhesions between the bladder and uterus. Other surgeons have claimed to cure it by the simple division of cicatricial bands on one side or the other of the urethra or neck of the bladder.

Fischer's operation, which is the new one described by Flouquet, is a liberation of the meatus laterally and inferiorly. An incision is made along each side of the meatus and prolonged for more than an inch into the vagina. Then a strip of mucous membrane half an inch wide is resected from the outer side of each of these incisions. The urethrovulvovaginal band is divided and the part of the hymen or its remains, corresponding to the operative field, is resected. The lateral wounds are then sutured separately and a strip of gauze is inserted between them to prevent any possible adhesions between the right and left suture lines, and the vagina is filled with gauze. The patient is catheterized for twenty-four hours to avoid contamination of the wound, and is kept in bed three days. The tampons should be inserted daily for three or four weeks and the cicatrization carefully watched during this period. The results are said to be most satisfactory.

The Lawson-Tait Bedstead.—The late Lawson Tait, in the first number of a new medical journal, *The American Medical Quarterly*, which was published in New York in June last speaks of the advances which have been made in recent years in bedsteads. The change from the inconvenience and uncleanliness of the old four-poster, to the modern iron single bed, as we know it in all hospitals, and in a constantly increasing number of homes, was really the result of the education of modern nurses. Nearly twenty years ago Tait devised a bedstead with heavy woven-wire springs, steel side-bars and end-pieces, which is similar to the furniture used in hospitals to-day. He was an advocate, however, of a low bed both for the comfort of the sleeper and for that of the nurse in case of sickness. Seventeen inches from the floor to the top of the mattress he gives as the correct height for people of average size. To avoid sagging in the middle the frame which holds the spring is slightly arched, so that when the weight of a person is placed upon it it will be level. Under these circumstances it is easy for a feeble person to turn over on his side. Instead of castors he recommends rubber foot-pads.

Rectal Medication in Infancy.—GARRIGA (*Rev. de Therap. Medico-Chirurg.*, June 1, 1899) advocates rectal medication in young infants, on account of the rapid absorption by the rectal mucous membrane, and because of the difficulty of administering to an infant anything having an unpleasant taste. The best method is to introduce the desired remedy in a cocoa-butter suppository. In this manner the author has obtained excellent results, for instance, with the sulphate or hydrochlorate of quinin in eruptive fevers, grip, etc. The suppository will be melted in five minutes, and after that there is no danger of its expulsion.

THERAPEUTIC NOTES.

A Fat Man with a Diabetic Family History Recovers from Diabetes.—WEST (*Lancet*, June 3, 1899) tells of a large, stout man who had been for three weeks ill, with thirst, frequent micturition, and loss of weight. His urine was 1030, and contained 8 per cent. of sugar. He was put upon a strict diet and given a mixture containing cinchona and acid. In a month the sugar had all disappeared from the urine, and the thirst had gone. He was allowed to eat some bread. The sugar reappeared in small amount but he kept on with his bread, and soon the urine was normal. For a year he continued on a diet containing almost no sugar, but considerable starch. He was so well then that he was advised to try a mixed diet, which he did, remaining in perfect health

up to the time of report nearly two years later. This case is the more remarkable in that the mother and sister of the patient did of diabetes, at the ages respectively of seventy and thirty years, while a half-sister on the mother's side died of the same disease at the age of forty-eight years. The case also illustrates the rule that if the patient is going to improve on a diabetic diet, the improvement will manifest itself in a short time.

Ascites Due to Hepatic Cirrhosis Cured by Operation.—MORISON (*Lancet*, May 27, 1899) has operated in four cases of ascites due to cirrhosis of the liver. In one the diagnosis was doubtful, and in another renal complications brought about the death of the patient in eleven days. In two uncomplicated cases a complete cure was the result. One of the patients died two years later after an operation for ventral hernia, and as the abdominal organs were injected before the peritoneum was opened, the resulting specimen showed very plainly how successful had been the attempt to establish new channels for the venous blood from the surfaces of liver, spleen, and omentum, to the parietal peritoneum. In some places there were veins the size of the radial artery in the cicatricial tissue as a result of the scraping and suturing at the operation two years before. Morison concludes that it is no longer advisable to treat patients with ascites due to cirrhosis of the liver by repeated tappings, but that if one or two tappings have failed, an attempt should be made to establish adhesions between the liver, spleen, and omentum, and parietal peritoneum. His cases show that such adhesions are filled with blood-vessels, which will persist if there is need of them.

Treatment of Muscular Rheumatism —OSLER ("Practice of Medicine") says that rest to affected muscles is of the first importance. Strapping the side will often relieve the pain of pleurodynia. In acute lumbago acupuncture is the most efficacious treatment. Needles three or four inches in length (sterilized hat-pins will answer) are to be thrust into the muscles at the seat of the pain and left for five or ten minutes. Very often the relief given by this procedure is instantaneous. At the outset a Turkish bath will frequently cut short the attack.

Treatment of Acute Inflammation of the Middle Ear.—BISHOP ("Diseases of the Ear, Nose, and Throat") says that in the first stage, before the pain has become intense or effusion has occurred, the ear should be gently inflated and the canal filled with pure, warm vaselin. The patient should be kept in bed and given morphin, gr. $\frac{1}{6}$, with atropin, gr. $\frac{1}{400}$. A solution of cocain, 10 to 20 per cent. may be dropped into the canal. The bowels are to be evacuated and leeches applied in front of the tragus and behind the auricle. No oil, onion-juice, or other domestic remedy should be allowed in the canal, nor should poultices be applied, as they favor the occurrence of suppuration. Fever calls for the use of antipyretics, but quinin should not be used. To allay the pain the use of the following simple device is often successful: an ordinary clay pipe is partly filled with tobacco and lighted, and a piece of thin cloth put over the bowl. A loose plug of cotton having been lightly inserted in the meatus the end of the pipe-stem is gently rested against the plug and the warm smoke driven through this into the canal by blowing into the bowl. If rupture of the drum is threatened it should be freely incised in the postero-inferior quadrant. A 20-per-cent. solution of cocain should be left in the canal for twenty minutes previous to the puncture of the membrane, and applied afterward if the pain persists. After the pain has ceased the ear should be gently inflated daily for a few days as the air-pressure promotes absorption of the products of inflammation.

Treatment of Subacute and Chronic Gout —To check excessive formation of uric acid LUFF ("Gout; Its Pathology and Treatment") recommends attention to diet and regimen, the promotion of metabolism of the liver, and the relief of congestion of the portal system. Colchicum in small doses, with guaiacum resin, gr. v–x, in capsules should be given three times a day, and an occasional pill at bedtime of blue mass and enonymin, followed next morning by Epsom salts. If there is atony and debility of the stomach nux vomica with potassium citrate is indicated. Iron preparations are, as a rule, not well tolerated by the gouty, but if anemia is present the citrate of iron and ammonium or the carbonate of iron will be appropriate. To promote the elimination of uric acid free diuresis should be encouraged by the use of large quantities of water. Table-salt should be avoided as much as possible. For enlarged and tender joints iodid of potash, gr. v–x, with tincture of iodin, *m.* v–x, should be given three times daily. Guaiacum should not be used when marked inflammatory symptoms are present. The lithium salts are not useful except as powerful diuretics. The possibility of organic renal disease must be kept in mind constantly.

Repose in Bed in Alcoholism.—MAGNAN (*Rev. de Therap. Medico-Chir.*, June 1, 1899) says that repose in bed is one of the best sedatives for cerebral excitation occurring in acute or subacute alcoholism. The predominant phenomena of these troubles are the illusions and hallucinations, and these are increased if the patient is kept in the dark, while if he is kept in the light, only the fixed objects about him are associated with his imaginings and forms which are wholly fanciful are relegated to a secondary place.

Treatment of Simple Pharyngitis.—BISHOP ("Diseases of the Ear, Nose, and Throat") advises the following: The patient should be given a tablet containing caffein, gr. $\frac{1}{6}$; morphin, gr. $\frac{1}{12}$, and atropin, gr. $\frac{1}{200}$, every four or six hours for a few days, or the following may be prescribed:

℞ Ammon. chloridi . . . gr. ii
Tr. opii camphor. }
Syr. scillæ comp. } aa . . *m.* v
Syr. tolu. }
Ext. glycyrrhizæ . . . gr. iiss.

These ingredients should be made into a tablet and allowed to dissolve slowly in the mouth. Quinin is not to be used. Gargles are inefficient.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, AUGUST 5, 1899.

SANARELLI ON THE SPECIFIC NATURE OF THE BACILLUS ICTEROIDES.

We have insisted in the editorial columns of the Medical News on the danger from yellow fever that inevitably accrues to the United States through her present occupation of infected islands in the West Indies. The recent epidemic among our soldiers at Santiago and the outbreak at the Soldiers' Home near Fort Monroe unite in bringing home to us the urgency of American interest in this problem. Though these outbreaks of the disease have been exaggerated by the sensation-loving newspapers there has been enough of seriousness in them to warn us of the danger that the new state of affairs has brought with it.

It is unfortunate under these circumstances that despite all the work which has been done on the subject the etiology of the disease still remains in doubt. It is the special policy of the Medical News to keep its readers thoroughly informed as to every phase of the discussion with regard to the pathogeneity of Sanarelli's bacillus in the disease. Though a number of seemingly trustworthy investigators have confirmed his discovery and the New York harbor quarantine department has founded a method of treatment of the disease on this theory, there still remain a number of experienced bacteriologists who do not consider Sanarelli's bacillus as the specific cause of yellow fever.

We are very glad then to be able to present a review of the whole subject to date from the pen of Sanarelli himself who is at present Professor of Hygiene at the University of Bologna. The article from the distinguished bacteriologist will appear in next week's issue of the Medical News. It comes to us as a tribute to the scientific discussion of the subject that has found a place in our columns at various times, and which Professor Sanarelli himself has followed with avowed interest. The discoverer of the bacillus icteroides considers himself now in a position to effectually dispose of adverse criticism concerning its specific pathogeneity and his very valuable original article on the subject will warrant general interest throughout the country.

VIRULENCE OF SPIDER AND OTHER INSECT BITES.

In this number of the Medical News we publish an abstract of a paper by Dr. Palmer Cole, read before the Harvard Medical Society of New York, in which he details his personal experience with a spider bite that proved very serious. At rare intervals in this latitude spider bites are inflicted that seem to possess a special virulence. There are a few species of spiders in the temperate zone which secrete a certain amount of poisonous or very irritating material and whose bite may set up considerable local disturbance. There is none, however, that could be expected to produce serious constitutional trouble unless in the presence of an extremely sensitive idiosyncrasy. As a matter of fact, any number of spider bites occur annually without any more than passing annoyance to the person bitten, and without even any marked local inflammatory reaction.

That serious results do sometimes follow even the bites of our domestic spiders, if they may be so designated, there is no doubt. A number of cases similar to that reported by Dr. Cole have been traced by most careful and capable examiners from the time

at which the bite was inflicted, and there could be no room for doubt as to the etiology of the constitutional symptoms that followed. Practically all of these cases have a decided similarity to those of ordinary septic infection resulting from operation- or dissection-wounds. There is the same slight inflammatory reaction for a time in the vicinity of the wound, then a period of almost absolute latency, lasting from twenty-four to forty-eight hours or even longer, then the signs of a spreading infection, a lymphangitis of the arm, perhaps, and finally the ordinary symptoms of septicemia, or at least of absorption of a certain amount of septic material. Flies often have an opportunity to alight on septic matter, bandages, dressings, and the like, containing the ordinary pus-cocci, or on animals dead from contagious disease. They become contaminated with it externally as well as internally, and then, in many instances, are devoured by spiders. It is a well-known fact in natural history that spiders are extremely cleanly insects. Certain species have been observed to clean themselves with as much solicitude and in a manner quite similar to the domestic cat. It is probably due to this reason that spider bites are not oftener serious in their results. Surgical cleanliness is quite beyond the spider's instinct, however, and so at times septic infection follows the contact.

The treatment of the lesions caused by a spider bite should be directed rather to the complications liable to ensue than to the actual bite itself. As in most insects the poison secreted by a spider is considered to be of an acid reaction, and the free use of ammonia, by counteracting the acidity, will relieve the irritation of the tissues most readily. If the only irritant introduced beneath the skin has been the spider virus, no further local treatment will be required, and the lesion will heal kindly and without giving further pain. If, after a period of latency, pain, slight throbbing, and an increasing area of redness occur, then the wound should be treated at once as an infected one and laid freely open. All the precautions should be taken in its treatment as would be considered necessary in a dissection- or operation-wound which showed signs of having become infected. Promptness and thoroughness, as is well known, count for much in the treatment of these conditions, and the same thing will be found to hold good in the case of spider and other insect bites, and patients will be saved serious sickness and danger.

THE POSITION OF THE SIGMOID FLEXURE.

THE sigmoid flexure is from both the medical and surgical standpoint an extremely interesting portion of the intestine. Its position at the end of the descending colon and its supposed tendency to provide a favorable place for the accumulation of feces makes it one of the convenient parts of the anatomy to which to accord the responsibility when congestive conditions of the lower limbs or of the genital tract or the rectal region are found to be present. Its importance in gynecological work because of its contiguity to pelvic structures and in intestinal surgery because of its frequent involvement in ileus and its deliberate choice as the point of election in the production of artificial anus make its anatomical relations of special interest. It is of great practical importance then, to note the expression of more recent anatomical views as to its position and relations.

Professor Gerrish in the recently issued "Text-Book of Anatomy by American Authors" has a very striking colored plate in which the sigmoid is seen dipping into the true pelvis at the left, crossing it transversely and rising on the right to curve backward and downward to meet the rectum. The old idea entertained by most medical men that the sigmoid occupies the left iliac fossa is rather rudely dispelled. The description given in the text is exactly in accord with the notion conveyed by the illustration, while an accompanying explanatory diagram emphasizes still more the idea that part of the sigmoid loop dips transversely across the true pelvis to rise out of it again before eventually descending from the right side posteriorly to meet the rectum.

The idea is of course not new, but the practical lessons it teaches have not, we think, been brought home fully to the great body of the profession. A good while ago Treves broke away from traditional descriptions of the position of the sigmoid and gave the one that he repeats in detail in "Morris' Anatomy":

> The normal position of the sigmoid or omega loop is not in the left iliac fossa but wholly in the pelvis. The descending colon ends just at the outer border of the psoas muscle. The bowel descends vertically along the left pelvic wall and may reach the pelvic floor. It then passes more or less horizontally across the pelvis from

left to right and commonly comes in contact with the right pelvic wall. It will be therefore in more or less direct contact with the bladder and uterus and may touch the cecum.

Treves' description is the one usually adopted now and is confirmed by so good an authority as Testut. Schäffer and Symmington, the editors of Splanchnology in "Quain's Anatomy," have not been so explicit in their description, but that is evidently due to the fact that relational anatomy is not especially dwelt on.

Kelly in his recent work on operative gynecology gives a very complete description of the sigmoid and its relations, especially to female structures, which he illustrates fully. He has found the relations of the sigmoid very variable in different individuals but with a decided tendency in all cases to wander to a goodly distance from the left iliac fossa in which it has been presumed to mostly lie. In one class of cases he has found it made a sigmoid curve behind both broad ligaments. In a second class it curves out into the anterior portion of the pelvis over the bladder, and then back to the sacrum. In a third class there is an extension up into the abdomen as it crosses from left to right of the pelvis and the descent of the bowel is from the right. Finally in a fourth class the sigmoid passes in front of the uterus almost to the region of the right round ligament where it curves backward to reach the promontory of the sacrum, at which point it makes a plunge down into the pelvis.

It is evident that the varying positions of the sigmoid and the important place it occupies in relation to pelvic structures generally must make it of even more consequence medically and surgically than has been thought. The clinical study of the influence of the sigmoid in the light of these newer anatomical details in various pathological conditions of itself and of contiguous organs can scarcely fail to clear up a number of obscure affections in the pelvic region generally and prove a source of knowledge of the greatest practical importance.

ECHOES AND NEWS

A Typhus-Fever Epidemic.—There were thirty new cases of typhus fever at Loeftan, Germany, on July 26th, making a total of 150 cases.

A Public Fund for Bacteriological Research.—Efforts are being made in France to secure by public subscription a fund for bacteriological research. A few rich corporations have already subscribed a total of 78,500 francs.

The Plague in India.—It was reported on July 31st from Bombay that the plague is raging at Poona, where, in forty-eight hours, there were 59 new cases and 56 deaths in the city, and in the cantonment 301 new cases and 261 deaths.

"Divine" Healing of No Avail.—Mrs. Edward Flanders died of "blood poisoning" at St. Luke's Hospital, Chicago, on July 29th, after having been attended by Mrs. Bratz, a "divine healer." The State Board of Health of Illinois has notified its attorney to investigate the case.

Sick Soldiers from Manila.—The transport "Morgan City" arrived at San Francisco on July 24th from Manila with 473 soldiers on board. When the vessel left Manila all the men were sick or wounded. On her arrival all but thirty were able to be on deck. Three men died on the voyage.

Miscegenation in Washington.—A daily statement is published in Washington, D. C., of licenses issued for marriage. There have been but two departments, one of white persons and the other of colored persons licensed to marry. On July 24th a third was organized, for white and colored.

Men Wanted for the Hospital Corps.—There is said to be a dearth of applicants for enlistment in the Hospital Corps of the new regiments for service in the Philippines. In time of peace, at any rate, this part of the service is rather unpopular among the rank and file. Whenever the jokes run scarce, the "hospital corpse" is made the subject of such delicate and gentle raillery as is characteristic of the army private.

A Hospital for Consumptives.—The Reverend Dr. Robert McIntyre, pastor of St. James' Methodist Episcopal Church of Chicago, announced on July 24th that a wealthy and prominent man, who wished his name withheld, will use part of a large fortune in erecting a hospital for incurable consumptives. This building will be a memorial to the donor's daughter who died after much suffering from consumption.

London Poisoning Case.—An inquest into the cause of death of Mr. F. W. Bartlett of Philadelphia was begun in London on July 28th. On July 17th Mr. Bartlett after dining at the Inns of Court Hotel was taken sick, as were thirty four fellow diners. Dr. Munford, who attended a number of them, found them ill with gastro-enteritis. The poisoning seems to have been either from American tinned apricots or from gooseberry ice cream. Mr. Bartlett died on July 26th.

What Is the Matter with Lombroso?—Lombroso's sanity is being questioned, and not without reason. He has written an article for the August number of the *Pall Mall Magazine*, entitled "An Epidemic of Kisses in America," in which he tells of Hobson's "10,000 kisses," of their publicity, and of how he was at the time addressing "a

crowd of specially elite persons." Lombroso states that "Hobson began his career of kissing at Vassar College," etc., etc. A scientist should be sure of the primary facts from which he makes deductions.

Reported Birth of Seven Children.—The report comes from Brownsville, Penn., to the effect that Mrs. George Hackett, colored, gave birth a few days ago to seven children, four girls and three boys. They were all alive when born, but all died within a few hours but one. The reports say they were small, but well formed. The parents are poor, the father being a miner, and about twenty-five years old. The mother had two children before giving birth to these. She is said to be doing well, and the one child will probably live.

Rabies in Erie County, New York. — According to the statement made at Albany on July 27th by Commissioner Weiting of the State Agricultural Department the worst outbreak of rabies reported in many years in now raging in Erie County. People, dogs, horses, and cows are suffering. Four of the present inmates of the Pasteur Institute in New York City are from Erie County. A large St. Bernard dog, belonging to a man living in Albion, is responsible for the spread of the disease. He ran wild for some forty miles before he was shot.

Queer Life-Insurance Case.—One Thomas Chase is supposed to have died at Milligan, Tenn., in February last, leaving to Mrs. Chase a life-insurance policy of $30,000. This the life-insurance company paid, but through its attorney it seeks to recover this amount, alleging that Chase did not die as was reported, and that a wax figure was buried as his body, that he was probably the victim of a hypnotist who worked in collusion with the beneficiary to secure the insurance money, and who probably spirited Chase away while he was under hypnotic influence.

Legal Status of a Legacy to a Physician's Wife.—A patient in Van Rensselaer County, N. Y., during his last illness devised all his real estate to the wife of his attending physician. Two days before his death and while suffering greatly from heart disease he also willed her his personal property. Some fifteen years before he had made a will in favor of his relatives but this he cancelled. The surrogate of Van Rensselaer County has revoked the probate of the will, holding that the presumption of undue influence which exists between physician and patient had not been overcome, that no sufficient explanation had been given for the exclusion of the sisters to the advantage of a stranger and that the probate allowed without contest must consequently be revoked.

The American Association of Obstetricians and Gynecologists.—This Association will hold its twelfth annual meeting at Indianapolis, Indiana, September 19, 20, and 21, 1899. Many valuable papers have been promised, and the meeting is sure to be an exceedingly interesting one. A committee of arrangements has been organized, consisting of a number of physicians of Indianapolis, under the chairmanship of Dr. L. H. Dunning, and the management of the Denison House offers the special rate of $3 without bath, and $3.50 with bath, a day, American plan, to members and guests of the Association who attend the meeting. The Denison House will also provide an excellent room for the meeting. Dr. Edward J. Ill of Newark, N. J., is president of the Association, and Dr. William Warren Potter of Buffalo, N. Y., secretary.

Antivaccination Crusade.—There are English antivaccination eccentrics who are rather prematurely wearing halos, being entitled thereto by the martyrdom which they are undergoing. A case was opened on July 28th in the Court of Queens Bench in London. The "Leicester Guardians," consisting of 35 men and 5 women, appeared to show cause why a mandamus should not be issued to compel the appointment of a vaccination officer. These guardians were elected under a pledge to resist compulsory vaccination. During their journey to London crowds of sympathizers met them at various stations and cheered them vociferously. In London they were met by huge crowds, who cheered the "Leicester martyrs," and accompanied them to the court, having formed a procession for that purpose. The Court, however, mandamused them.

Typhoid-Fever Statistics.—The New York State Board of Health has been analyzing the figures for this State to find in what localities typhoid fever has been especially prevalent. The disease is usually found more in rural districts than in cities. The rate in the small towns and country districts in 1897, was 149 and in 1898, 174 deaths in 10,000. The cities do not all have a lower rate than the rest of the State, and the Board, in a tabulation of the death-rate figures, groups them for convenience into three classes: those having a rate below that of the rural districts, those having about the same rate, and those having a decidedly higher rate. In the first class, cities having a low rate of deaths in each 10,000 deaths in 1897 are placed New York, Brooklyn, Yonkers, Utica, and Auburn; in the second class, Buffalo, Rochester, Syracuse, and Troy; and in the third, Albany, Elmira, and Binghampton. In most of the cities, as in the State at large, there was in 1898 a decided increase in deaths from typhoid fever, and 6 of the 12 cities had a higher rate than the rural districts in the same year.

The Ohio "Hygeia Medical College."—The question of the competency of this college to grant degrees in medicine and surgery was raised recently in an action brought against that institution by the Attorney-General of Ohio. The defendant's charter empowers it to educate "suitable persons in the art and science of curing disease by the use of air, baths, electricity, heat, magnetism, massage, and all other resources of Nature." It was contended by the Attorney-General that this language was too general to apply to courses of medical and surgical instruction such as are given in schools of good standing and repute, but the Supreme Court of Ohio decided against him, saying that it is not made to appear that any subject taught by the faculty is beyond "the resources of Nature." However, the expression is not one that would naturally

be selected as indicative of a purpose to teach medicine as practised ordinarily. The agencies of cure mentioned in the charter seem rather to exclude the idea of employing artificially compounded drugs; and the Attorney-General seems, therefore, justified in having attempted to restrict the activities of the institution.

A New Pathological Institute for Oxford.—Oxford has long been in need of increased facilities for the teaching of pathology. This has been strenuously urged on several occasions recently, notably by Sir John Burdon-Sanderson, but the funds for the purpose were not in the University treasury. Not long ago a friend of the University offered to contribute £5,000 to the Pathological Department if as much more were provided from other sources. The University congregation decreed at a recent meeting to supplement the contribution of the generous anonymous donor by £5,000, so that a new Pathological Institute for the University seems assured. Building operations cannot be begun until after the University convocation has passed on the matter but no opposition is anticipated. It is confidently expected that within a year Oxford will be provided with a pathological department that will yield to none in its completeness and the facilities it will afford for teaching and investigation. A fund for the furnishing of apparatus to the new laboratory is being enthusiastically contributed so that it is evident that a new era in pathology is about to open up for the University.

Lawson Tait and His Position in the Profession in England.—A great deal of capital has been made in recent years by the Antivivisectionists out of Lawson Tait's adherence to their views. Our London correspondent a short time ago touched in his usual happy trenchant style upon the Antivivisectionist epitaph that the distinguished surgeon ordered in his last will and testament to be placed over the vault in which his ashes rest. The following words and appreciation of Mr. Tait's career in recent years, from the pen of one of the ablest of medical editors, that of *The Practitioner* (London), will be of interest to our readers: "Another surgical writer who was always readable, however much one might differ from the opinions and sentiments which he expressed, has passed away in poor Lawson Tait. Nature had been prodigal of intellectual gifts; and assuredly he did not hide his light under a bushel. Yet his last years were spent in a fruitless struggle to regain a lost position. In one way he was *felix opportunitate mortis* (blest in the moment of his death) for his professional sun had well nigh sunk below the horizon. What this occultation was due to is a subject which I do not feel called upon to discuss, nor is it for me to enforce the moral of his career."

A Step in the Right Direction.—The following is from an editorial in the June, 1899, issue of the *Medical Times*, (homeopathic): "However valid may have been the reason in the early days of the homeopathic school for identifying its institutions with a distinctive sectarian name, it is a matter worthy of the most careful consideration, if, in the present advanced and ever-advancing state of medical thought, when the most accurate scientific tests are being applied honestly and faithfully to every principle in medicine, and to every new thought developed in the wide range of studies connected with our profession, the retention of that name in our colleges and hospitals does not retard their influence and create in the minds of scores of students in after years a feeling of regret that in a profession ever broadening in its scope and becoming more and more a unit in its work, their diploma, in name at least, is a distinct sectarian one, and out of tune with that broader liberty which looks upon the whole world as its own. There is no disputing the fact, for the records are open to all, that every year many, very many physicians, on whose diplomas the name Eclectic or Homeopathic appears, seek and obtain from other colleges a non-sectarian degree, in which no pledge is required or implied of adherence to any one dogma, and giving perfect liberty for that freedom of action based upon a careful education and mature thought. At the commencement of the Cleveland College of Physicians and Surgeons last month, no less than fifteen homeopathic physicians secured the diploma of the college after having spent the winter in study."

Yellow Fever Near Fort Monroe.—On July 31st it was reported that yellow fever had broken out in the National Soldiers' Home, between Hampton and Fort Monroe, Virginia, in which about 4,000 veterans reside. There have been forty cases on the reservation and seven deaths from the disease have been reported. The United States authorities at Fort Monroe have already quarantined against the Soldiers' Home, and street cars running through the town of Phœbus, adjoining the Home, are not permitted to enter the Government reservation at Old Point Comfort. Newport News and Hampton have already taken steps to quarantine against the Soldiers' Home, and rigid regulations will go into effect at once. Dr. Samuel W. Hobson, quarantine officer at Newport News reports that the disease is beyond doubt yellow fever. The authorities of the Home readily admit the fact and no effort will be made to withhold from the public the real nature of the situation. Surgeon General Wyman of the Marine Hospital Service says that he will go to Hampton in a few days to take charge of the work, if it is decided that it is genuine yellow fever. The Government will adopt strict precautionary measures to prevent the spread of the disease, and will fight its progress with all the skill and resources at its command. Dr. Wyman has sent Surgeon White of the Marine Hospital Service to take charge. Surgeon Wasdin, one of the yellow-fever experts of the service recently returned from Cuba, happened to be visiting Norfolk, and he has been ordered to duty. Surgeon Wedenbacker, stationed at Wilmington, N. C., has also been ordered to Norfolk, so as to be available for any duty for which he may be required.

The Cancer Problem.—Dr. Woods Hutchinson of Buffalo, now in London, has published the second of a very interesting series of medical articles in the July number of the *London Contemporary Review*. The first paper, a very suggestive essay on cellular biology, appeared in the

April number under the title "The Republic of the Body." The present article, on "The Cancer Problem," is a very timely popular exposition of the subject of cancer which is at present of more than passing interest on account of Professor Roswell Park's declaration that cancer is very rapidly on the increase, which was published simultaneously in the MEDICAL NEWS and *The Practitioner* of London, and attracted a great deal of attention. One remark in Dr. Hutchinson's article will we think be highly suggestive even to medical men. "If we strike out the mortality from cancer of the mammary gland and of the uterus and its various appendages in women and that from cancer of the mouth-parts, that is, the lips, tongue, larynx, etc., in men, the cancer mortality will be almost exactly equal in both sexes. Curiously enough, the mouth-parts take on a development about the age of puberty in man that corresponds more or less to the development of the internal genital apparatus in woman. It is true this development is not one of actual tissue increase so much as functional evolution. The larynx grows larger, the vocal cords longer and coarser, the throat and lips enlarge, and the palatal arches, soft and hard, develop so as to make the characteristic deeper voice of the adult male. If would seem that the liability of these two sets of structures to cancer about the time when involution of the organism begins, bears a definite relation to their functional development about the time of puberty."

MEDICAL MATTERS IN NEW YORK.

DEATH FROM HYDROPHOBIA — MIRACULOUS CURES EXPECTED FROM KISSING A HOLY RELIC — FREQUENCY OF HYDROPHOBIA, ACCORDING TO THE S. P. C. A.—ILLUSTRATING THE REPORTS OF THE BUREAU OF MUNICIPAL STATISTICS—QUARTERLY REPORT OF THE BOARD OF HEALTH.

AN interesting trial of the Buisson treatment for hydrophobia was made a few days since. George M. Bockoven, fifty-six years old, the captain of a tugboat, was bitten in the right hand by a mongrel dog on June 12th. There were seven wounds in all, and they bled very freely. They were cauterized with carbolic acid and quickly healed. The man suffered no inconvenience until July 23d, when he began to feel considerable pain in the right arm. Three days later he could not swallow water or food, and respiration was interfered with. On July 27th the symptoms of hydrophobia were so pronounced that his physicians decided to resort to the so-called Buisson treatment, the period when antitoxin might have proved efficacious having passed. The patient was put in a steam bath at 120° F. for half an hour, and then rolled in blankets, where he was allowed to remain several hours, when the hot bath was repeated. Small doses of morphin were given to quiet the spasms. There was absolutely no favorable result from this treatment, and the man died in great agony the following day.

On July 26th, from early morning until night, men, women, and children passed before the shrine of St. Anne, mother of the Blessed Virgin, in the little red brick French church of St. Jean Baptiste, in East Seventy-sixth street. Their object was to kiss a relic of the saint, a piece of bone from her forearm, which the Curé, the Rev. Frederic Tréteau, obtained seven years ago from the church of St. Paul outside the Walls at Rome. Many of the devotees were on crutches, or leaning painfully on walking-sticks, some were blind, some deaf, and some sufferers from many other ills. Father Tréteau said that it had not come to his knowledge that any miraculous cures had occurred.

John P. Haines, president of the American Society for the Prevention of Cruelty to Animals, has contributed an article in the current number of *Our Animal Friends*, published by the Society, on "Rabies and Hydrophobia." He says: "Hardly any phrase in the English language is more misleading or has done more cruel injury to man and beast than 'dog days.' There are no days on which and there is no kind of weather during which a dog is peculiarly liable to rabies. Rabies is a rare disease at all seasons of the year, and there are no more cases of rabies in July or August than in December or January. It follows, therefore, that there is no more reason to dread our family friend, the dog, in hot weather than in cold, and no more reason to dread hydrophobia from his bite at one time of the year than at another.

"Genuine hydrophobia is one of the rarest of all the diseases by which humanity is afflicted, and rabies, the canine disease from which hydrophobia is supposed to be contracted, is also one of the rarest diseases of the dog. Medical men of eminence have not hesitated to say that there is no such disease." Dr. Charles W. Dulles, Lecturer on the History of Medicine at the University of Pennsylvania, is quoted as saying that he has failed, "after sixteen years of investigation, to find a single case of hydrophobia on record that can be conclusively proved to have resulted from the bite of a dog or any other cause."

As to the Pasteur treatment, Mr. Haines puts forth Dr. Dulles' assertion that "so far from having diminished the number of deaths from alleged hydrophobia, they have actually increased since the date of his supposed discovery." Says Dr. Dulles: "There has been added to these a large number of deaths due to inoculation of the virus of what ought to be called 'Pasteur disease.'" Dr. Dulles believes that the Pasteur method has done nothing whatever to diminish hydrophobia, but rather, on the contrary, that it has done much to increase it. [This is rather interesting in view of the success generally attributed to inoculative treatment for the prevention of hydrophobia. We are almost tempted to believe that Dr. Dulles has been incorrectly quoted.]

Dr. John Nagle, Chief of the Bureau of Municipal Statistics, has devised a scheme for illustrating the annual reports of the bureau with photographs of all important works.

The report of the Board of Health for the quarter ending March 31st, published July 26th, shows that during the first three months of the year the number of marriages in this city was 4877; births, 12,608; deaths, 9436. During the quarter 162 persons committed suicide, 55 of them by taking carbolic acid, 34 by shooting, 30 by inhaling gas, 17 by hanging, and the others by stabbing,

drowning, leaps, and poisons of various kinds. Of the 162 suicides 117 were men and 45 women; 62 were natives of Germany, 49 of the United States, 10 of Ireland, and the others were of various nationalities.

MEDICAL MATTERS IN PHILADELPHIA.

FREE ANTITOXIN FOR THE POOR—NEW BUILDING OF THE JEFFERSON MEDICAL COLLEGE—EXAMINATION OF NAVIGATORS FOR COLOR-BLINDNESS—NEW PHYSICIANS IN THIS STATE—ENTERIC FEVER AT CAMP MEADE—SMALLPOX NEAR PITTSBURG—AN EPIDEMIC OF ANTHRAX—LEHIGH VALLEY MEDICAL ASSOCIATION—HEALTH REPORTS.

THERE has been such a perceptible increase in the prevalence of diphtheria in this city during the last few weeks that the Board of Health has decided to take practical measures to prevent, if possible, the further spread of the disease by offering to supply antitoxin free of charge to all physicians who may require it for use in their practice among the poor. A circular letter to this effect, signed by the president of the Board, was sent to all physicians of this city last week, and a supply of diphtheria antitoxin is now kept at the various district police stations, at the disposal of the medical profession at large.

The new building of the Jefferson Medical College, which has been under construction during the past fifteen months, is now practically completed and will be formally opened at the beginning of the fall term of the school next October. It is intended to make this occasion one of significance in the history of the institution, in that it marks the first practical step in the entire reconstruction of the college. The exercises will be presided over by Dr. T. Addis Emmet of New York and the principal address is to be delivered by Dr. Phineas S. Connor of Chicago. Distinguished members of the medical profession are expected to be present. The building which has just been completed is situated at the corner of Tenth and Walnut streets, and has a depth of 118 feet and a frontage of 107 feet. It is of Italian Renaissance architecture, five stories in height, and constructed chiefly of brick, limestone, and terra cotta, with a steel skeleton. The old hospital will next be torn down and a modern edifice erected corresponding in design to the new college building which it will immediately adjoin.

Under an act of Congress passed at its last session, and which went into effect the first of this month, the medical officers of the United States Marine Hospital Service in this city are engaged in examining for color-blindness the captains and mates of all sailing craft of more than 700 tons register hailing from this port. This examination is preliminary to the examination by the port authorities for navigation licenses, and such licenses will be refused to applicants failing to present certificates from the Marine Hospital surgeons to the effect that the holder is not affected with color-blindness.

The statement just issued by the State Medical Examiners, giving the results of the recent examinations for licenses in this State, cannot fail to reassure the public that there will be no dearth of doctors in Pennsylvania this year at least. Of the 425 applicants examined, 375 were successful, and were duly granted licenses to follow their chosen profession in Pennsylvania. Apropos of this question, it is of interest to reflect upon the fact that the share which each member of the State Examining Board derives from his labors in conducting these examinations has been approximated at no small sum. At $25 each, the present fee which each candidate must pay for examination, the total amount to be divided among the members after expenses have been paid cannot be far from the sum of $10,000. And it cannot be remarked in seriousness and truth that the examiners' labors are particularly onerous. This is one instance, and a rare one at that, in which the medical man is not underpaid and as such is unique.

Current reports speak of an outbreak of enteric fever among the recruits at Camp Meade, the large army camp of instruction a few miles from Harrisburg. Major Woodruff of the Army Medical Department who is in charge of the medical matters there attributes the outbreak to infection brought to the camp by new recruits, and states that as everything in the camp is in excellent sanitary condition no fear of the spread of the disease exists. With echoes of the deplorable epidemics at Camp Alger and Chickamauga last summer still ringing in its ears the War Department has by this time undoubtedly learned and *heeded* the lessons of camp sanitation and will take steps to insure the healthfulness of present mobilization points for troops such as Camp Meade.

Smallpox is rife in several parts of Pennsylvania, especially in the small towns and villages in the neighborhood of Pittsburg. In that city and in Allegheny sporadic cases are becoming too numerous to be ignored, and the prevalence of the disease in other nearby communities is thought by some of the Western health officers to threaten an epidemic next winter unless immediate measures are taken to stamp out the malady wherever is now prevails and by strict quarantine prevent its transmission from town to town. Dr. R. L. Taylor of Pittsburg who represents the State Board of Health in that vicinity and who has just completed a tour of inspection in the Western end of the State, is quoted as saying that smallpox in this section exists in almost every village along the line of the Pittsburg, Cincinnati, Chicago and St. Louis Railroad, the majority of the patients being either concealed by their relatives or the disease improperly diagnosed by the local physicians. An urgent appeal has been made to the State authorities to act in the matter, and to provide sufficient funds to end the epidemic.

An epidemic of anthrax has broken out among the live-stock in Bedford County, and it is also reported that two men have been infected with the disease. The outbreak is attributed to the importation of hides, infected with anthrax, by the Leather Trust, which operates tanneries in this county. Dr. Leonard Pearson, State Veterinarian, is investigating the situation.

The nineteenth annual meeting of the Lehigh Valley Medical Association was held at Glen Summit, July 27th. Sixty-five members were in attendance. The election of officers for the ensuing year resulted as follows: Presi-

dent, Dr. Israel Cleaver of Reading; vice-presidents, Drs. C. P. Knapp of Wyoming, J. H. Halber of Pottsville, O. H. Sproul of Flemington, and A. A. Seen of Bangor; secretaries, Drs. Charles McIntire of Easton, and W. P. Walker of South Bethlehem; treasurer, Dr. Abraham Stout of Bethlehem. The retiring president Dr. J. H. Bauman of Telford delivered an address on "Tuberculosis," and Dr. W. L. Rodman of Philadelphia read a paper on "The Early Diagnosis and Treatment of Tumors of the Mammary Gland."

The total number of deaths occurring in Philadelphia during the week ending July 29th was 481, of which number 112 were of children under five years of age. During the week the reports of contagious disease were as follows: Enteric fever: 43 new cases, 8 deaths; Scarlet fever: 41 new cases, no deaths; Diphtheria: 43 new cases, 10 deaths; Cerebrospinal meningitis: 1 new case, 1 death. The total number of deaths is a decrease of 29, compared with the number reported last week, and an increase of 16 over the corresponding period of last year.

CORRESPONDENCE.

DECOMPOSITION OF CHLOROFORM BY AN OPEN FLAME.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—$COCl_2$, phosgene gas, not chlorin, is produced by the influence of flames upon chloroform vapor. This effect I discovered and described many years ago. It causes tickling in the throat and in many, nausea and vomiting. This, to correct Dr. Winslow's statement, cited in the MEDICAL NEWS of July 1, 1899, page 13, relative to poisoning from chloroform decomposed by an open flame.

BUFFALO, N. Y., July 25, 1899.

THE APPLICATION OF THE "ROD METHOD" IN AUSCULTATION OF THE LUNGS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In the MEDICAL NEWS of July 8, 1899, I directed attention to a simple method of measuring the intensity of the heart tones. The method in brief consisted in the introduction of a rubber rod into the pectoral end of the stethoscope. The length of the rod determines the intensity of the cardiac tones, the latter becoming less distinct as successive rods of increasing length are employed. In my previous communication I advocated the method in its application to the heart tones. My investigations since then demonstrate the practical application of the "rod method" in auscultation of the lungs, not only as a means of measuring the intensity of the acoustic lung phenomena as in the case of the heart tones, but for purposes of diagnosis.

A simple illustration will suffice. We will presume that in auscultating the apices of the lungs some slight difference is noted in the respiratory sounds between the two sides. This difference may consist only in an increase in the loudness of the vesicular murmur, yet our stethoscope *per se*, is too gross an instrument to depend on in establishing this difference. In instances like this, and they are not infrequent, the "rod method" possesses insuperable advantages. If through a rod, let us say ten (10) centimeters in length, the vesicular murmur is conducted to the ear of the auscultator, whereas with the same rod the murmur is inaudible on the corresponding side in the same area, we are justified in concluding that in one of the apices there is an exaggeration of the vesicular murmur. This is a rough, though not impracticable, method of diagnosis. ALBERT ABRAMS.

SAN FRANCISCO, July 19, 1899.

[Translation.]

SEPARATION OF THE AMNION AND CHORION.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I have read with great interest the article by Dr. J. B. Nichols, on the separation of the chorion and amnion, published in the MEDICAL NEWS for July 1, 1899, I have been much interested in this question, and have published a memorandum regarding it in my work on obstetrics, volume 2, pages 378 and 423. To this description I would refer one for further information on the subject.

I explain the separation of the amnion and the chorion in the following way: During labor the chorion partially ruptures at the uterine orifice, and the pocket of waters formed by the amniotic membrane is forced through the ruptured chorion, forming a hernia. Drawn down and contracted by this hernia the amnion is peeled off from the chorion, and if this peeling off continues long enough, of course, the membranes are completely separated, one from the other.

I think that this explanation, which, it seems to me, was unknown to the author of the article, may be of interest to him as well as to others of your readers, which is the reason I have written you.

I beg you to accept the assurance of my kindest regards.

DR. AUVARD,
Accoucheur de l'Hôpital Saint Louis.

PARIS, FRANCE, July 20, 1899.

NORMAL SALT SOLUTION ENEMATA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—In his article on shock, published in the MEDICAL NEWS for February 25, 1899, Dr. Dawbarn lays great stress on the use of normal saline solution intravenously. His point is well taken, that too little attention is given by the majority of operators to the care of the patient after operation. For the past three years in my hospital practice it has been a routine method with me of ordering a hot nutrient-stimulating enema after every abdominal section as soon as the patient has been returned to bed. In many cases the enema has been ejected during the restless recovery period from anesthesia, and in this event the orders to the nurse were to repeat it as soon as the restlessness had passed off.

This practice has undoubtedly been serviceable and a life-saving measure in many cases.

For more than twenty years I have been in the habit of using simple warm water by the rectum in all cases of severe loss of blood from whatever cause, and the absorption has always been fairly rapid, but not comparable to that of normal salt solution. The latter was interdicted even in the half-per-cent. strength for fear it would induce action of the bowels. When various statements were made in regard to the rapid absorption of the normal salt solution by the tissues I considered the advisability of substituting this for the nutrient enema and giving it in large quantity, but, like the nutrient enema, it was given during the recovery period and was rejected, yet very much less frequently, and it certainly acted more promptly. Yet even when thrown very high up in an empty bowel it would be rejected during the period of recovery-excitement, even though constant pressure was made to the fundiment. When retained absorption was very rapid.

During my last term of service at St. John's Hospital (March, April, and May) I decided to order as a routine practice 8 ounces of saline solution before the patient left the operating-table so as to insure absorption before the restless period of returning consciousness should supervene. This has worked with perfect success, as I have not known an instance in which the solution has been rejected by the rectum when thus administered. During this service it was used in between fifty and sixty instances in which capital operations had been performed. In three apparently hopeless cases in this term of service I attribute the recovery almost entirely to the use of the saline enema. In these cases the quantity used in half an hour amounted to three or four quarts.

In ordinary cases the 8-ounce enemas are repeated every two hours for at least sixteen hours after operation, and longer if the patient's condition seems to require it. If nothing else could be gained by the use of the saline enema the mitigation of post-operative thirst would be a full and sufficient reason for giving them. The same object is gained by the intravenous use of the normal saline solution, and before I became sure of the *rapid* absorbing power of the rectum and large intestine for the saline I was in the habit of using it by the brachial vein. Now I use both in desperate cases.

About eighteen months since, after a very extensive abdominal section, the patient became pulseless at the wrist. I opened the median basilic vein, and per cannula, introduced into the circulation in the course of an hour and a half, 2½ quarts of the normal saline solution. This was prepared at a temperature of 115° F., but in passing through the tube it loses 10° of heat and probably enters the circulation at a temperature not higher than 105° F. Should it enter at a higher temperature it would do more harm than good. In the case above referred to 4 quarts were given by the rectum in the same period of time. The patient made a good and rapid recovery, having no bad symptoms after her recovery from the shock. The beauty of the rectal method of administration is the rapidity with which it can be administered.

The patient will have absorbed a quart of solution by the bowel before the cannula can be gotten ready, the arm prepared, the vein opened, and the cannula introduced. The tube, bag, saline, and the *rectum* are always ready for instantaneous use and no operation is required. If the patient has been properly prepared the bowel is always empty and ready to absorb a fluid with the proper osmotic properties which the normal saline solution undoubtedly possesses.

OUR LONDON LETTER.

[From Our Special Correspondent.]

SUPERSTITION AS TO "UNCLEANLINESS" AT THE MENSTRUAL PERIOD—SPITEFUL ARREST OF A DOCTOR—NEW CHARTER OF THE ROYAL COLLEGE OF SURGEONS—PENSION TO MRS. KANTHACK—"POISON BY POST" SENTENCE—HOSPITAL FOR PAUPER CONSUMPTIVES—DEATH IN THE STOKE-HOLE OF A MAN-OF-WAR.

LONDON, July 24, 1899.

THE University of London, with its prospect of a really high-class medical school for the metropolis, with a Post-Graduate and Research Department, has materialized sufficiently to obtain suitable buildings the past week at the Imperial Institute. This is a splendid building just north of the Natural History Museum at South Kensington, which had become a white elephant on the hands of the Government, so that all parties are pleased by the decision.

A curious superstition has just been revived here by quotations from an Australian paper, which objected to the admission of women physicians to the staff of a certain hospital on the ground that "at certain physiological periods" they become "a source of danger" to surgical patients. It actually goes on gravely to state that Lister, in his earlier experiments, was completely baffled in his attempts at antisepsis by this malign influence exerted by the nurses at certain times and that it was only by "carefully watching for and eliminating" this that success was attained, all of which is, of course, pure legend and shows how hard superstitions die. A belief of this sort is widely spread among the laity and probably owes its origin to the religious ordinances of various cults, according to all of which a woman, during her menstrual flow, is ceremonially unclean, and in some communities compelled to isolate herself completely.

A member of our profession has just had the honor of a special mention, indeed an entire debate to himself in Parliament, though whether the distinction was worth what he paid for it is more than questionable. Dr. Lamont of South Uist, Scotland, a medical man who some years ago attracted wide attention by his devotion and bravery during a frightful epidemic of typhus, staying to nurse his patients when even their relatives had fled, incurred the dislike of some members of his Board of Guardians (Supervisors). They watched for their opportunity with petty spite, and finding a child to whom he had given a certificate of vaccination, which did not show a well-marked scar, they had him arrested on a criminal

charge of issuing a false certificate, late on Saturday afternoon, so that he laid in jail all Sunday. When brought up for trial the jury acquitted him at once and the bringing up of his case in Parliament by our leading medical member, Sir Charles Cameron, aroused such a storm of indignation from both sides of the House that not only the Lord Advocate or Attorney-General for Scotland, but also Mr. Balfour himself promptly declared that the local law-officers should be severely censured and the question of adequate compensation to Dr. Lamont be carefully considered.

The election at the College of Surgeons resulted in both the "provincial" (non-Londoner) candidates being defeated and both the London ones elected, which is a fair sample of the onesidedness and petty prejudice of the Fellows, most of whom are London consultants. This reduces, we believe, the representation of all England outside of London upon the Council to three members.

At the annual meeting of both Members and Fellows the President, Sir William MacCormac, presented the draft of the proposed new charter, which completely ignored the reasonable demands of the Members for a voice in its affairs and begged the latter with Pecksniffian and almost tearful pathos not to raise any captious objections for fear of disturbing the harmony of the coming centenary. This gauzy plea which meant the deferment of any justice to Members until the Council chooses to ask the crown for another charter, say about the next centenary, hoodwinked nobody and the meeting promptly voted by a large majority to return the proposed charter to the Council, with a request to enlarge its powers in accordance with a memorial which would be presented. As, however, under the present intentionally oligarchic charter only the Fellows have votes or can sit in the Council and they are extremely loath to admit any one else to share in their ancient privileges, just or unjust, the chances of any reform being effected are but slight.

The Government has granted a Civil List pension of $300 a year to the widow of the late Professor Kanthack, the brilliant young English pathologist who died a few months ago at Cambridge.

Under the new Compensation Act the accidents in factories, quarries, and mines, still continue to increase, 780 fatal ones in the past eleven months, as against 612 for the corresponding period a year ago. Most of this, however, is believed by the Home Secretary to be due not to increased recklessness on the part of the men, but to the improvement of trade and consequent greater pressure of work or larger number of new men employed.

Both the experts who examined Mary Ansell, hung last week for the poisoning of her sister, declared themselves unable to find any ground for regarding her as insane, and as against the statement of Drs. Nicolson and Brayn, both of Broadmoor Asylum, there is nothing to be placed except the mouthings of that spectacular alienist, Forbes Winslow, who was sure she was a "degenerate" without ever having examined her. Public opinion generally acknowledges the justice of the sentence. Almost the only exception is the well-meaning but unbalanced *Daily Chronicle*, which came out with an editorial shriek a column long, protesting in tones that remind us of our own transatlantic hysterics on the same subject, against the execution of *any* woman, for no matter what crime! "Degenerate" is a very pretty term of such elastic application that it can be made to apply to almost any case, and like the bulk of the Lombroso-Nordau vernacular is of little more scientific value than "crank." Certainly it is utterly insufficient to base a plea of irresponsibility upon, in the case of a deliberate cold-blooded murder for a purely mercenary object. If this be "degeneracy" then it is an element which the law does well to assist in eliminating.

The tuberculosis crusade is spreading steadily. A few weeks ago the Poplar (London) Poor-Law Guardians applied to the Local Government Board to know if they had the power to establish a special poorhouse hospital for the treatment and care of pauper consumptives. For a wonder the central authority raised no opposition to a change and informed them that they had the power and might make a charge upon the Metropolitan Common Poor-Fund at ten cents per day for each patient. So a departure will shortly be made in the direction of establishing much needed homes of refuge for indigent consumptives. Even if it be only as a place where the poor creatures can die in comfort it will be an enormous boon, for, especially since the spread of the infection-theory, it has become a matter of great difficulty, for not merely poor but even moderately well-to-do patients who have no family or home of their own, to find a place in which they can die in peace. We have known wealthy sufferers in the last stages driven out of room after room, house after house, the moment their condition was discovered, and Dr. Trudeau of the Adirondack Sanitarium stated two years ago that next after hospitals for the early stages the most crying and even more pitiful need was homes of refuge for the hopeless cases. Many a poor fellow has come to him, and with tears in his eyes, begged to be told of some refuge where he could purchase the privilege of dying in peace.

A sad case has just been reported from one of the ironclads of the Reserve Fleet at Torbay. A stoker, named Finn, joined the ship July 6th; two days later complaint was made that he was not keeping up his fires properly. On being reprimanded he said that his "heart was bad," whereupon he was brutally told that he must either see a doctor or do his work like the rest. He chose the latter and inside of an hour was found insensible in a coal-bunker and died the same evening. The temperature in the stoke-hole was *only 109°* F., which is considered "cool" on an iron-clad, according to the Chief Engineer!!

These stoke-holes, not only on iron-clads but also in Atlantic liners, have long been a disgrace to civilization, and it is high time the law interfered, first to insist upon some arrangement for a current of cool, fresh air, and second that no man should be allowed to enlist as stoker without a medical certificate of entire soundness of heart-valves. Several instances are now on record in which young fellows anxious to work their passage have joined the crew as shovelers and died on the voyage from the heavy work in heat and foul air.

TRANSACTIONS OF FOREIGN SOCIETIES.

German.

CHYLOTHORAX, TRAUMATIC, AND SIMPLE—TROPICAL ANEMIA AND ITS RELATIONS TO MALARIA—MODERN OPERATIONS FOR UTERINE MYOMATA.

AT the Free Union of Surgeons of Berlin, May 8th, HAHN spoke of a case of chylothorax occurring in a man who was run over. Difficulty in breathing followed, and dulness on the left side of the chest. Aspiration gave exit to a rosy-red fluid, which afterward became milk-white. During the forty-two days that elapsed before the man's death thirty-six liters (quarts) of fluid were aspirated. The autopsy showed a fracture of the eighth and ninth ribs, and dislocation of the seventh rib and of the cartilage between the ninth and tenth vertebræ. The tear in the thoracic duct was demonstrated by injection. Eight cases of traumatic chylothorax, five of which terminated in recovery, have been previously reported. Often the accompanying injuries have been so severe as to make recovery impossible. Chylothorax of a non-traumatic character has also been reported, but as far as known has only twice been followed by recovery. In both of these instances it was due to pressure of tubercular or syphilitic lymphatic glands upon the thoracic duct.

At the Berlin Medical Society, May 31st, PLEHN spoke of tropical anemia and its relations to latent and manifest malarial infection. Europeans who go to tropical countries often suffer from symptoms of anemia without being really sick. This has been explained as a period of acclimatization, but no one has offered an explanation as to the pathological processes which occur, and exact comparison of the number of blood-corpuscles, of percentage hemoglobin, and specific gravity of the blood, in foreigners and in natives have been said to show that no anemia exists in the sense that the older writers supposed. The pale color of the skin has been thought to be due to the care used in avoiding the sunlight. Entertaining these views Plehn was not a little surprised to find that the new comers in Kamerum, on the West coast of Africa, did show a diminution in hemoglobin up to twenty per cent. soon after their arrival, or in the first month or two. Later there was a rise followed by a fall, or the amount varied from time to time until the period when malaria developed. Continuing his investigations for two years he made nearly 2000 examinations of the quantity of hemoglobin, of the specific gravity of the blood, and of the microscopic appearances of the blood. As to treatment he found that iron had no effect on the anemia. Arsenic improved the appetite somewhat, but produced no other effect. In many cases the regular use of quinin every five days did much good. A change of air from the coast to an inland station is beneficial, although in profound anemia it is not advisable to take a patient direct to high mountains.

As the anemia in both Europeans and coast negroes is not to be attributed to the climate, and does not come in the wake of any severe illness, it must be supposed to be due to some specific cause. Plehn found changes in the blood-corpuscles in almost every person affected—both native or European. Stained with acid alum-hematoxylin-eosin the corpuscles showed a number of deep blue points, and similar bodies were found free in the plasma or in pairs or short chains. These bodies increased in size and number until the individual was attacked with malaria. Immediately afterward they were scanty or failed altogether, even though the patient received no quinin. Later they reappeared, and were sometimes found months or even years after the individual had passed from the sphere of malarial influence, or had shown any symptoms of malarial fever. Apparently they reproduce themselves in the blood. Plehn looks upon the bodies as the seeds of the malarial parasites, which by development in the red blood-corpuscles lead to the destruction of the latter. Under favorable circumstances they develop into plasmodia and produce a malarial attack—a life history which can be observed microscopically if the observer has the good fortune to examine the blood two days before the first attack. The development of the parasites is closely analogous to that of the pyrosoma bigeminum of Texas cattle fever. Plehn believes that the different forms of malaria have one common cause. He also rejects the idea of different varieties of black-water fever. As the latter shows a strong tendency toward recovery without treatment it is not necessary to administer quinin to patients suffering from it. Still as quinin or enquinin is the only remedy in malaria, its use ought not to be omitted in malarial attacks for fear that black-water fever will follow. He expressed himself as against the mosquito theory on the ground that the half-moon-shaped form of parasites is the only one carried by mosquitoes, and parasites of that form were very rare in his region.

At a meeting of this Society held June 7th, CZEMPIN spoke of modern operations for uterine myomata. Many physicians are still prejudiced against them on account of the high death-rate which followed operation ten years ago, and also because they trust too much to the benign character of the tumor. These tumors not so infrequently undergo malignant degeneration. Moreover, the hope that symptoms will disappear at the climacteric is often illusory.

Of the vaginal operation, enucleation is easy if the myoma is polypoid; permissible, if more than half of its back lies in the uterine cavity, but is bloody and dangerous otherwise. Vaginal hysterectomy is too well known and liked to need an advocate. It had better not be employed if the enlarged uterus is too great to pass the vagina without cutting it into pieces. Certain operators have had brilliant successes to record from morcellement and vaginal hysterectomy, but there have been many lives needlessly sacrificed by this method.

Of the abdominal operations, enucleation with suture of the surrounding tissues may be performed for one nodule after another, so that the uterus may be left even in rather complicated cases. Such a procedure has its limits, however, and a very much torn-up uterus had better be removed, especially as one has no guarantee that other rudimentary nodules will not grow forthwith. In the early days of abdominal hysterectory the cervix was left as a pedicle, on account of fear of hemorrhage and sepsis. Now it is known that it carries its own dan-

ger in the shape of necrosis produced by ligature to control hemorrhage. Most operators are therefore agreed upon its removal, either abdominally or vaginally, after the closure of the abdomen. The results of supracervical amputation are better now than they were in the days when aseptic technic was less perfect, but they are still much inferior to total extirpation and must ever remain so.

SOCIETY PROCEEDINGS.

HARVARD MEDICAL SOCIETY OF NEW YORK.

Regular Monthly Meeting, Held March 25, 1899.

THE President, DR. HENRY C. COE, in the Chair.

The paper of the evening, on

ACUTE PURPURA HEMORRHAGICA,

by DR. S. K. BREMNER, owing to the author's unavoidable absence, was read by the Secretary, DR. J. B. WALKER. The author accepts the classification of acute purpura hemorrhagica, suggested some time ago by Lockwood, into essential and sympathetic. Most of the cases come under the latter head, the symptoms being due to certain drugs, as quinin, iodin, arsenic, and the salicylates, and to various infectious diseases, as diphtheria, smallpox, and the exanthemata generally. The following case would seem to come under the head of symptomatic purpura: A child, six months old, breast-fed, who had constantly gained in weight, began to fail. Then a hemorrhagic spot appeared on the occiput and another on the bridge of the nose. The day these were noted the patient's temperature was 99°, the next day it was 101°, then 102° F. The bowels were irrigated with the idea of preventing the further absorption of toxins from the intestine, if this was a cause of the hemorrhagic condition, and also to eliminate certain toxic substances from the blood by increased exosmosis. The child grew paler from day to day and the purpuric spots grew larger and more frequent. Some blood was vomited and some blood-clots and clear blood passed by the rectum. Great prostration supervened on these losses of blood, and finally death occurred from exhaustion. The urine had continued normal during the whole course of the affection. The autopsy failed to show intracranial hemorrhagic lesions, or ulcers of the gastric or intestinal mucous membranes. There was a good deal of congestion of the lower parts of the lungs.

The whole picture, clinical as well as anatomical, was that of an infectious disease. There was the invasion after prodromal weakness and malaise, the progress to an acme followed by exhaustion, and then the absence of any serious organic lesions, at autopsy. Under the term purpura hemorrhagica are probably included a series of different infections which act upon the blood and the blood-vessels so as to allow diapedesis. It is in the blood that observers have looked for bacteria in this disease and their search has been rewarded by finding various micro-organisms. A bacillus looking not unlike the bacillus of anthrax and one resembling the bacillus aerogenes capsulatus have been found. At times several microbic varieties have been found in the same case, and it is possible that the disease is polymicrobic in origin.

The microbes may produce the purpuric lesions directly, as by acting on the walls of the blood-vessels in a particular region, or they may be due to a toxemia, the toxins produced by bacteria causing changes in both blood and solid tissues. That the disease is contagious seems clear since it occurs in groups in hospitals and in at least one recorded instance a brother and sister suffered from it at the same time.

The changes in the blood are quite marked. Clot formation is different from the normal, and this may be partly explained on the ground that the hematoblasts are more infrequent than in normal blood, for it is now generally recognized by physiologists that these play an important part in clot formation.

Treatment in the case of children as a rule seems of little avail. A number of remedies have been recommended, of which most is claimed for iron and general tonic treatment. Whatever of benefit was derived from drugs in the case reported was from these remedies. Ergotin has been used with success.

It is claimed that patients have been cured by the injection of 250 c. c. of serum, by the administration of thyroid extract, and by hypodermic injections of ergot. In general, however, it is admitted that the disease in children is usually fatal despite all remedies.

In the discussion which followed DR. HOLDER said that he had seen a good many cases of purpura on Randall's Island. In adults quinin seemed to do good, but in children the affection nearly always proved fatal no matter what line of treatment was adopted. A great variety of remedies had been employed. As in none of the cases were any purulent conditions observed it would be extremely hard to imagine that pyogenic micro-organisms, as so many have claimed, could be the cause of the disease in all cases.

The reason why the adults improved under the use of quinin seemed to be because malaria was the cause of the purpura, the changes induced in the blood by the malarial parasite being sufficient to permit hemorrhagic exudation in spots, which characterizes the disease. Quinin was given freely, *i.e.*, in doses of from 20 to 30 grains a day, according to the individual.

In the case of the children there was evidently some other cause at work, for the quinin did not have the same therapeutic effect. The disease seemed to have a tendency to occur in groups and to affect especially a single ward at a time so that there was little doubt of its contagiousness. It bore very interesting relations to pemphigus which also occurred epidemically on Randall's Island. Some time ago a doctor and two nurses had been infected by the contents of some blebs and had had a characteristic attack of the disease but had recovered without at any time having manifested serious symptoms.

Therapeutic experience on the Island had rather fostered the idea that there is no specific medication for these hemorrhagic conditions in children. A good many different remedies reported to be successful in the hands of others had failed to give the desired results there. So-

called hemostatic and hematogenic remedies seemed to be effective only inasmuch as they were also tonic in action. General tonic treatment seemed to do the most good. Quinin, in doses of 10 grains or more, three times a day, seemed the best routine treatment, the indication seeming to be to cinchonize the patient as soon as possible, and to keep him in a mild stage of cinchonism for some time.

DR. ROYAL WHITMAN said that it is very necessary to differentiate cases of scurvy from purpura. Joint pains, in addition to the hemorrhages, seem to occur in both. Of late many cases of scurvy had been reported as the result, not of feeding children on the patent foods, as used to be said, but from keeping them too exclusively on a diet of sterilized milk. The cure of these conditions as a rule is comparatively easy. All that is necessary is to change the patient's diet to one of raw or modified milk. It is almost marvelous to see the change that comes over most of the little patients even after only a single day of the alteration of the diet. In some cases this scorbutic condition seems to develop even in children that are fed at the breast. In these cases additions to the diet are needed.

DR. SCHRAMM, who reported two cases of purpura hemorrhagica in detail, said that he also had seen cases of scurvy after an exclusive diet of sterilized milk. The longer the milk had been heated, as a rule, the worse have been the cases, and they had been a shorter time in developing. Mothers, when told to heat the milk, usually concluded that the longer it was heated the better it was and the surer not to effect the child's health. A good deal of sickness and malnutrition among infants seems due to this cause.

Meeting of April 22, 1899.

The paper of the evening was read by DR. PALMER C. COLE and was entitled

ACUTE PURPURA HEMORRHAGICA IN THE ADULT. REPORT OF A CASE OF POISONING BY SPIDER-BITE IN THE ADULT.

The case of acute purpura the speaker reported was the only one he had had the misfortune to see in more than forty years of practice. The patient was a robust and seemingly healthy individual, forty-three years of age, who had spent the hours from 8 to about 11 one morning in cleaning out a rather deep tank that had not been used for three or four years. He had then quit work because he felt weak and was nauseated. He had not been completely overcome while in the tank and had been able to help himself and find his way out. At noon he vomited a number of times and felt so weak that he took to his bed. He did not undress, and after taking some whisky seemed to feel better. There was a recurrence of nausea after a time and he grew weaker, so that shortly after 2 P.M. he sent for a physician. The speaker saw him before 4 P.M. and found him rather dull and heavy in mind, not easy to arouse, but when aroused able to answer all questions intelligently.

The important thing about his appearance was the presence of a number of petechiæ, some of them of large size. There were bright hemorrhagic spots on his groins and thighs, some of them as large as two or three inches in diameter. A number of spots of the same kind were noted on his mucous membranes also. Apparently nothing seemed able to arouse him from the gradually deepening lethargy into which he sank. The hemorrhagic spots continued to increase in number and size and at 8.30 P.M. the patient died. A consultant who had been called in confirmed the diagnosis of acute purpura hemorrhagica, probably due to the inhalation of some poisonous gas while working in the disused tank.

The Board of Health made an investigation into the cause of the accident, but was unable to discover it, although it was considered by its experts also that some noxious gas or gases was the cause. It would seem reasonable to conclude, then, that the blood-dyscrasia that leads to the appearance of purpuric spots may be brought on in fulminant form in seemingly healthy individuals by the respiration of mephitic gases. This may help to throw some light on the slower running cases, and seems to indicate that in ordinary cases the hemorrhagic symptoms are due to toxins absorbed from the gastro-intestinal tract or from some focus of infection and that treatment should be directed by this indication.

The case of spider-bite was a personal experience of the speaker and was serious enough to dispel any doubts he might have had as to the verity of certain at least of the reported cases of extremely bothersome and threatening symptoms following spider-bites. In the tropics there is no doubt that spider-bites are frequently followed by serious consequences, though they are seldom or never fatal. Of late years we have learned that insects may be the carriers of disease germs, even though not themselves possessed of noxious qualities. The unfortunate experience in our camps during the late way with Spain showed that the ordinary horse-fly may be a most prolific carrier of disease germs from latrines, etc., and distribute them widely with serious consequences.

It has long been known that anthrax or malignant pustule can be and often is caused by the sting of the blow fly. In this case the insects seem able to carry the most deadly ptomains from the carrion on which they have been feeding, and inoculate their victims with serious, often fatal results. At first the possibility of such extremely virulent toxins being carried by insects was doubted and the connection between the bite and the resulting disease was looked upon as merely incidental, but experimental observations have confirmed it so often in recent years that there is no longer room for doubt as to the agency of insects as carriers of infective material.

Stories of spider-bites, with serious or even fatal results, have appeared so often in the newspapers, to be denied later, or at least to prove guiltless later of the essential elements of substantiation, that people generally, even physicians, have come to look upon them as bits of sensation unworthy of credence. The writer said that he was very glad to be able to detail his personal experience with a spider-bite that produced very serious symptoms and might easily have been worked up into a most sensa-

tional bit of news, the main facts of which, however, would have been substantially true.

About nine o'clock of a summer evening, while sitting on the piazza of his residence, he felt a sharp sting over the region of the first joint of his little finger. The stinging sensation continued for some time and was so severe that he examined the spot with a lens, but noticed nothing special except a slight redness. He applied a few drops of ammonia fortior and the pain grew less. He slept well but was wakened early by the pain which could now be felt throbbing and shooting up the back of the hand. The redness had increased in size and had now become an areola with a whitish dome in the center. In the midst of the white parts, by the aid of a hand lens, two black specks could be seen, which proved to be the claws of the spider. They were removed with pincers and on careful examination with the lens were seen to be jet-black, highly polished claws, and with no signs of extraneous material on them. There seemed to be serum in the whitish elevations, but incision for it was not successful.

During the day, while slightly painful and tender, there were no further symptoms from the sting, but on the second morning he was distinctly ill with constitutional disturbance, lassitude, and loss of appetite. The inflammation extended to the wrist by this time and there were some chilly feelings. A small incision down to the bone in the finger was made and a small amount of white inodorous pus was evacuated. The next morning there was a sharp rise of temperature and great constitutional disturbance, though the pain was no longer annoying. The inflammation had now extended up to the elbow and the hand and finger were laid freely open, being placed afterward in a bowl containing 1 to 1000 mercuric bichlorid, which was gradually reduced to 1 to 2000, and then 1 to 4000. The axillary glands became enlarged and the shoulder somewhat involved by spread of the inflammation to the soft tissues around it.

On the seventh day after the bite complete subsidence of all the symptoms took place and only the little finger remained painful and tender. Desquamation took place over the whole arm. The skin over and near the finger desquamated three times and the bite did not entirely heal for eight weeks.

The practical points in the case are its comparatively latent, slow progress for the first two days, then the fulminant character assumed by the symptoms on the third day, which diminished somewhat on the fifth day but did not disappear until the seventh day. The history of the case is not unlike that of malignant pustule. In that affection the point of infection is usually the upper lip and for the first two days, except for the swelling which is so prominent because of the character of the tissues here, and so annoying because of the abundance of sensitive terminal nerve endings in the part, there are no symptoms to speak of, then suddenly on the third day there is serious constitutional disturbance, a pyemic condition sets in and death may supervene suddenly on the fourth day.

All arachnidæ, even those in our temperate climate, have a poison apparatus by which they are enabled to quiet the struggles of their insect victims and protect themselves against a host of insect enemies. A minute droplet of venom is ejected from the poison-sac of which it takes but little to kill a fly. Ordinarily the deaths from spider-bites have been discredited, but the knowledge of these facts of natural history and the present case show the possibility of serious results even from simple spider-bites. Orfila, who has devoted a good deal of time to the study of spider-bites says that certain cases take on a septic character. It is evidently one of this class of cases that we had to do with here.

In answer to the question as to the variety of spider, and as to whether it was surely a spider, Dr. Cole said that the variety was not especially studied. Such a bite might have been produced by a small viper, but while spider-bites cause pain at the moment viper-bites do not. There had been an immediate stinging sensation that would have called attention to anything that caused the bite had it been other than a spider.

DR. FISK, in the discussion which followed, said that while a few insect bites of various kinds are treated in the out-patient department, as a rule, very few of them are of more than passing interest. Human bites are, however, not frequently followed by very annoying symptoms. In these cases it is evident that it is not any poisonous substance previously existing in the mouth that sets up the serious inflammatory disturbance, but that a living germ present in the flora of the mouth is inoculated into the wound at the time of its infliction, and finding in the tissues a favorable culture medium proceeds to multiply, with the production of the serious symptoms so often noted. These will depend on the pathogeneity of the germ introduced and may be only local in character, but may be and often are constitutional. In a recent case of this kind the wound had been received by the patient's hand striking against the other's teeth. This is not an uncommon way for the infection to be acquired and sometimes the inflammatory reaction set up spreads to the tendon-sheaths and ties up the tendons, laming the hand for life. Such cases need prompt and thorough surgical intervention. The site of the wound should be promptly laid freely open as soon as serious symptoms begin to manifest themselves. A great deal of annoyance and danger will thus be saved.

DR. MITCHELL said that snake poisoning had been treated most satisfactorily by means of permanganate of potash and he thought that perhaps in these cases the injection of permanganate around the seat of the lesion would be indicated.

DR. COE said that most of us had seen spider-bites without any serious results following and it would seem that in a case like the one reported some extraneous, perhaps septic, micro-organism had been inoculated into the tissues at the time of the insect bite. It seemed more rational to think this than to assume the injection of a very virulent poison that had lain practically dormant in the tissues for two days and then taken on suddenly and without any known reason a fulminant toxic character.

DR. COLE, in closing the discussion, said that it is the custom of medical authorities to discredit the reports of

spider-bites followed by serious symptoms. In the present case, however, every detail seems beyond cavil. It does not seem to have been a septic infection and it was certainly not due to ptomains gathered in decaying material by the insect. It must be remembered that there are in this latitude one or two species that are distinctly poisonous, more poisonous than the scorpion of the South though we are apt to think of scorpion bites as always fatal.

Dr. Dillon Brown reported two rare and interesting cases that had come under his observation recently. The first was that of a child of healthy parents which had always been healthy itself until it was attacked some months ago by an extensive dermatitis exfoliativa. Accompanying the dermatitis was a furunculosis and a good deal of itching. The appetite was good, the bowels regular, and no cause could be found to explain the origin of the cutaneous condition. It was not congenital but has developed during the child's second year, and there is absolutely no question of hereditary influence in the case. None of the various remedies recommended seemed to do any good. Oil baths slightly carbolized which was the last thing prescribed seemed to control the itching somewhat.

The second case was one of diabetes in a child, aged four years. The child had as high as six per cent. of sugar in the urine, and had the intense thirst and frequent and copious urination of typical cases of diabetes. Under an absolute meat diet all the symptoms disappeared, and no trace of sugar has been found in the urine now for over a month. The absence of glycosuria and of any symptoms of diabetes justifies the expression that for the time at least the child is cured. Dr. Rotch of Boston who had seen the patient in consultation advised the continuance of the absolute meat diet for some time.

In discussion Dr. Palmer Cole said that he congratulated Dr. Brown on the excellent result produced by the meat régime. Personally, however, he has no confidence in the persistence of the cure. Children, in his experience, affected by diabetes always die. Occasionally, but not often, much more rarely, for instance, than in adults, there are remissions in the course of the disease but they do not last long and the ultimate prognosis is absolutely fatal. While there is life there is hope, however, and as it is probable that certain cases of diabetes in children were missed in the past owing to defective examination of the urine it may be that some patients have recovered unbeknown as it were.

REVIEWS.

Gout: Its Pathology and Treatment. Founded on the Goulstonian Lectures on "The Chemistry and Pathology of Gout." By Arthur P. Luff, M.D., Lond., B.Sc., F.R.C.P. New York: Wm. Wood & Co., 1899.

We welcome this publication as a very valuable addition to our literature and predict for it a prompt and wide recognition. It presents the logical deductions from a long series of laboratory experiments, supported by a large clinical experience. The work is thoroughly original throughout. It is divided into four parts. Part I., reproduced from the author's Goulstonian lectures, deals with the pathogenesis of gout. A critical review of various experiments into the pathology of the disease and the theories based upon them prefaces a detail of the author's own experiments.

He develops the following facts: "Uric acid does not and cannot exist in the blood in the free state under any conditions whatsoever." "Sodium quadriurate is the soluble uric-acid compound which is originally contained in the blood" and, being an unstable body, "unites with some of the sodium carbonate of the blood to form sodium biurate which . . becomes deposited in the various tissues. . . The phenomena of gout result, not from overproduction, nor from diminished destruction of uric acid, but from its *deficient excretion*. This deficient excretion is due to a functional affection of the kidneys, which may subside or may develop into an organic lesion. In health, uric acid is formed in the kidneys, probably from urea and glycocine brought from the liver, hence the association of liver troubles with gouty dyspepsia. No constant ratio exists in a given individual between the excretion of uric acid and urea."

Part II. is devoted to the etiology of gout, its various clinical manifestations, their diagnosis and prognosis. It is disappointing in its brevity. Part III. details the author's numerous experiments on the influence of various bodily conditions, and of various foods and drugs on the solubility and precipitation of uric-acid salts.

These investigations were, for the most part, carried on in the laboratory but they are more rather than less convincing than unchecked clinical experiments. The results are rather startling and upset many accepted doctrines. The author thus unequivocally summarizes his findings The alkalinity of the blood is apparently not appreciably diminished during a gouty attack; the solubility of uric acid in the blood is not affected by a diminished alkalinity of the blood; the deposition of sodium biurate is not accelerated by a diminution of the alkalinity of the blood; an increased alkalinity of the blood does not increase the solubility of deposits of sodium biurate; the gout-inducing properties of certain wines are not due to their acidity; they probably owe their gout-inducing action to the effect they exercise on the metabolism of the liver; the solubility of sodium biurate is markedly increased by the presence of the *mineral constituents* of most vegetables; solubility of sodium biurate is diminished by the presence of the *mineral constituents* of meat; the mineral constituents of certain vegetables delay the conversion of sodium quadriurate into biurate; the vegetables most useful to gouty subjects are spinach, Brussels sprouts, French beans, winter cabbage, Savoy cabbage, turnip tops, turnips, and celery. He condemns the administration of the ordinary alkalies, of lithium salts, of piperazine, and of lysidine, with the object of removing gouty deposits as useless. The author finds that no relationship exists between the acidity of the urine and the alkalinity of the blood, and he thinks that the administration of salicylates with the object of removing gouty deposits

is useless, and their employment in the treatment of gout contraindicated.

The fourth part of the work deals with the practical application of the above and other principles to the treatment of gout in its various forms. Here, again, the author casts out, without further apology, all accepted therapeutic measures which his experiments have proved to be chemically or physiologically unsound. Topical applications or internal administrations, exhibited with a view to dissolve uric-acid deposits in joints are rejected because uric acid as such is not the gouty deposit, and sodium biurate, which is, does not react to uric-acid solvents. The chemical properties of natural mineral waters are discussed at some length, elucidating the value of each of the European springs in the alleviation of the various gouty conditions. We recommend Dr. Luff's little book for its originality, pointedness, and scientific merit.

THE MEDICAL COMPLICATIONS, ACCIDENTS AND SEQUELÆ OF TYPHOID OR ENTERIC FEVER. By HOBART AMORY HARE, M.D., B.Sc., Professor of Therapeutics in the Jefferson Medical College of Philadelphia; Physician to the Jefferson Medical College Hospital. With a special chapter on the "Mental Disturbances Following Typhoid Fever." By F. X. DERCUM, M.D., Clinical Professor of Diseases of the Nervous System in the Jefferson Medical College. Philadelphia and New York: Lea Brothers & Co., 1899.

THE book before us is one that may be consulted with profit by all clinicians, dealing as it does with a subject of much importance to every active physician. The literature has been searched thoroughly and we doubt whether any complication of typhoid fever that might have escaped the author's personal experience has been omitted from the work.

The book is divided into seven chapters, the first chapter dealing with a general consideration of the subject, including several interesting statistical tables that show conclusively that typhoid fever is on the wane, both in its frequency and mortality. This is undoubtedly due to improved sanitation and our recognition of its etiology. The following chapters are devoted to the varieties of onset, the complications during the disease, the complications during convalescence, the conditions which ape typhoid fever, the duration of and immunity from second attacks, and the mental complications. Subdivisions are made to allow for the discussion of complications of the various organs.

In a future edition the question of immunity will very likely receive a more extensive consideration. So much is being accomplished in the field of immunity in an experimental line, that we trust the near future will place the whole question on a more rational basis.

The chapter on the mental complications by Dr. Dercum contains much of importance not usually to be found in text books. On the whole, the book is deserving of much popularity, written as it is by one who is entitled to speak with authority, and we heartily commend it to all practitioners.

THERAPEUTIC HINTS.

For Gastralgia.—

℞	Chloralis hydrat.	gr. xvi
	Sodii hyposulph.	gr. xl
	Aq. menth. piper.	℥ i.

M. Sig. One teaspoonful when indicated.—*Hare.*

For Prickly Heat.—

℞	Spts. etheris nitrosi, Magnesii sulphat. aa	℥ i
	Ol. cajuputi	*m.* i
	Syr. tolutani	℥ ii
	Aq. magnesii carb.	℥ ii.

M. Sig. One teaspoonful three times a day.

Tincture of Iodin for Acute Gastro-enteritis.—BIZINE highly recommends treatment by iodin in this affection both for adults and children. For the former he prescribes as follows:

℞	Tinct. iodi	gtt. xv
	Chloroformi	gtt. v
	Ol. caryophylli	gtt. vii
	Ol. menth. piper.	gtt. v
	Emuls. ol. ricini	℥ vi.

M. Sig. One tablespoonful every hour. Keep on ice.

When the chief symptoms have disappeared the above should be discontinued and the following given:

℞ Amyli iodat. . . . . ℥ i.

M. Div. in chart. No. VI. Sig. One powder every four hours.

If the symptoms are choleraic the following mixture should be given at once:

℞	Tinct. iodi	gtt. x
	Chloroformi	gtt. ii
	Ol. menth. piper.	gtt. iii
	Ol. ricini pur.	℥ v.

M. Sig. One dose

In addition hydrochloric-acid lemonade should be given and sinapisms and enemata employed if indicated. After abatement of the symptoms iodid of starch, as above, should be prescribed.

Diuretic in Chronic Interstitial Nephritis.—

℞	Ferri citratis	gr. lxxx
	Potassi citratis	℥ ii–gr. xl
	Syr. limonis	℥ i
	Aq. dest. q. s. ad.	℥ iv.

M. Sig. Two teaspoonfuls in water before each meal. —*Danforth.*

For Pseudo-Membranous Coryza.—

℞	Iodi	gr. iss
	Potassii iodi	gr. iv
	Ac. carbolici cryst.	gr. viii
	Tinct. opii	*m.* xv
	Glycerini	℥ iss.

M. Sig. For swabbing.—*Moure.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, AUGUST 12, 1899. NO. 7.

ORIGINAL ARTICLES.

SOME OBSERVATIONS AND CONTROVERSIAL REMARKS ON THE SPECIFIC CAUSE OF YELLOW FEVER.[1]

BY G. SANARELLI,
OF BOLOGNA, ITALY;
PROFESSOR OF HYGIENE AND DIRECTOR OF THE LABORATORY OF HYGIENE IN THE ROYAL UNIVERSITY OF BOLOGNA.

THE writing of the present paper was suggested to me by certain articles that I have read in the MEDICAL NEWS during the past year and which seem to indicate that a personal element has obtruded itself into the controversy which followed the appearance of my articles on the etiology of yellow fever. This personal element has made itself felt especially as a result of the attitude assumed by Dr. Sternberg in opposing the definitive conclusions drawn from my researches. It is true that in a recent article he has seen fit to modify his position considerably but he has not as yet withdrawn his opposition to my bacillus icteroides as the cause of yellow fever.

I respect Dr. Sternberg very much and have expressed my sincere appreciation[2] of the researches directed by the most modern scientific technic that he inaugurated on the subject of this important affection, yellow fever. I cannot understand, however, his obstinate unwillingness to concede that another has succeeded in solving the problem which proved unsolvable to him.

The first reclamations which the illustrious surgeon-general thought it well to make immediately after the publication of my original investigations, and in which he endeavored to maintain the identity of the bacillus icteroides as described by me with his bacillus X, are easy to understand and are such as might have been expected under the circumstances. But now that the question of the etiology and pathogeny of yellow fever has entered definitively into the domain of anatomico-clinical observation and of laboratory experimentation I believe it impossible to bring it back to the old ground and condemn on theoretic objections scientific conclusions.

No one knows better than I do myself how much work Dr. Sternberg did in his fruitless search for the pathogenic agent in yellow fever. I can understand then, that he would not readily concede success to another when he had himself failed. If it is true, however, that the man of science labors for the good of humanity and not for the sake of any personal satisfaction, or for self-glorification, then every laborer in the field of bacteriology can only rejoice sincerely at the successful issue of my studies. Unfortunately, this has not been the case.

It is not worth while now to go back over the old attempts to prove that the bacillus icteroides and Sternberg's bacillus X are the same micro-organism. Even Dr. Sternberg himself finally persuaded by the evidence of the facts and by the unimpeachable character of my demonstrations[1] has definitely renounced the idea of their identity with a scientific loyalty that does him honor[2].

My eminent colleague, however, gets no farther than this. He has abandoned only the first part of his opposing opinion and while conceding that the bacillus X and my bacillus icteroides are not identical, he cannot bring himself to admit that the bacillus icteroides is the causative agent of yellow fever. It must be remembered in this connection, however, that Dr. Sternberg's work on yellow fever was done some ten years ago, and that the youthful science of bacteriology has made wonderful strides in progress in that time. It will not be surprising then, if what seemed impossible at that time to Dr. Sternberg should prove comparatively easy of attainment in our day. Advances in technical methods in bacteriology made the circumstances of his investigations and mine quite different.

I have stated once before[3] certain reasons why there was not much probability of Dr. Sternberg's isolating and recognizing the bacillary cause of yellow fever during his original researches in the neighborhood of Havana. These, for there were more than one, I shall briefly repeat. Primarily Dr. Sternberg clung firmly to the idea that the seat of the specific virus of the disease was in the intestine. He seemed to have been of the opinion so commonly held by writers at that time, that a certain pathogenetic analogy existed between yellow fever and Asiatic cholera, the discovery of whose germinal cause had been such a triumph only a short time before. The symptoms and intestinal lesions which are observed in the two diseases are certainly sufficient to impose such an opinion on the observer, if he looks no further.

[1] Translated.
[2] *Annales de l'Institut Pasteur*, p. 438, 1897.

[1] *Centralblatt für Bakteriologie*, No. 22–23, 1897, and No. 10 1898.
[2] *Centralblatt für Bakteriologie*, No. 18–19, 1899.
[3] *Centralblatt für Bakteriologie*, No. 22–23, 1897.

That Dr. Sternberg held this opinion is clear, since in his report to the United States Government[1] in his official capacity he submits as one of his conclusions a suggestion for the treatment of the disease by disinfection of the intestinal tract, an alkaline solution of bichlorid of mercury of 0.02 per cent. being employed for this purpose.

This erroneous prejudice as to the pathogenetic mechanism of the disease was sufficient without doubt to influence the whole course of his researches. For it is evident that Dr. Sternberg yielded to the preconceived notion at that time so generally accepted, that it would be possible to isolate from the contents of the intestinal tract a microbic form that would be constant for the disease.

An analogous mistake though in an opposite direction had been made just a little before that by Emmerich with regard to cholera in his studies on Asiatic cholera at Naples. Impressed with the idea then sustained by the whole school of Pettenkoffer, that this disease spread through the air, he sought unsuccessfully for the specific germ of the disease in the circulation. It was from the blood vessels of the walls of the intestine not from their interior that he succeeded in isolating a bacillus. Further investigation showed that his famous bacillus Neapolitanus was only one of the ordinary fecal bacilli, which had by chance penetrated the walls of the intestine during the lowered resistive vitality incident to the terminal stages of the disease and so secured an entrance into the circulation. It was only a secondary infective agent not the primary cause of the disease that the discoverer had demonstrated.

It is true that Sternberg besides his investigations of the contents of the intestines made a number of cultures from the blood and the viscera, but it must be conceded by any one who reads the report of these researches in the light of modern bacteriological methods, that they leave a great deal to be desired from the point of view of our present day technical knowledge. Especially is this true when we consider how extremely difficult was the task he had set himself.

As a matter of fact his report to the United States Government contains only a description of a long series of microbes, that had been isolated, some of them directly from the blood and the cadaveric tissues of patients dead from yellow fever, but most of them from the blood or viscera of rabbits or guinea-pigs inoculated with hepatic juice, or with small quantities of the most contaminated material obtained from the stomach or intestines of yellow-fever corpses. It is evident that there would inevitably occur in the results obtained with such a primitive and defective technic very serious lacunæ, and such proved actually to be the case.

It is clear that microbes isolated after this manner in numbers, without any constant rule or uniform method, and summarily inoculated into animals on general principles must fail of individual recognition, and that the importance and specific characteristics of the micro-organismal cause of yellow fever, though present, must escape even the most sedulous attention under the circumstances. The bacillus of yellow fever must certainly have occurred in Dr. Sternberg's cultures a number of times, but it escaped his notice owing to his defective technic.

Dr. Sternberg himself now admits that during his investigations in Havana "the autopsies on yellow-fever cases succeeded one another so rapidly that a complete bacteriological examination of every case was practically impossible"[1] and that "the arrangement of his laboratory was so incomplete that it was impossible to keep animals under observation for more than five or six days after inoculation." Under these circumstances it is not hard to understand how his mission to discover the cause of yellow fever should have completely failed of its purpose.

It would seem only reasonable, then, that Dr. Sternberg, instead of trying to justify his own failure by systematically belittling the results obtained by others, should, on the contrary, be ready to admit another's success and use his influence to make the discovery better known. This impression was reproduced very vividly on me recently in reading the short note by Reed and Carroll, which was published in the MEDICAL NEWS for April 29, 1899, for their work it is announced was inspired by Dr. Sternberg himself.[2] In their article these two writers abandon as unsustainable the idea that the bacillus X and my bacillus icteroides are identical. They seek by every means in their power to damage the reputation of the bacillus icteroides and set it down as a variety of the bacillus *choleræ suis!* It is certainly not in order to demonstrate the extreme strangeness and improbability of this opinion that I have undertaken to write a new article on the subject of yellow fever, but in order to bring out clearly and denounce the levity of the critical methods habitually employed by obstinate opponents of my discovery.

I find it totally inexplicable that Drs. Reed and Carroll before attempting to launch such a paradox did not at least look up for a moment some good treatise on bacteriology, or better still, consult the classical original work of their distin-

[1] "Report on the Etiology and Prevalence of Yellow Fever," Washington, p. 85 1890.

[1] *Centralblatt für Bakteriologie*, No 6-7, p. 147, 1897.
[2] *Centralblatt für Bakteriologie*, No. 18-19, p. 660, 1899.

guished compatriot, Dr. D. E. Salmon, published in 1889 by the Government Printing Office in Washington and entitled "Hog Cholera, Its History, Nature, and Treatment." Had Drs. Reed and Carroll taken the time to do this they would have been at once convinced of the absolute impossibility of identifying two micro organisms which are readily differentiated, even by the crudest methods, from every point of view morphological or biological.

It is sufficient to recall that the bacillus of Salmon forms on potato a luxurious brownish-colored culture somewhat like that of mauve, while my bacillus icteroides develops on potato completely without color and is scarcely visible; it is enough besides to remember that the toxin of the bacillus icteroides resists a temperature of even 100° C., while that of the bacillus of hog cholera undergoes modification as low as 60° C. and is entirely destroyed at 100° C. The two toxins exercise upon animals a pathogenic action entirely different, as is evident from the studies of Selander and Metchnikoff [1].

We may recall besides that colonies of the two forms of bacilli on gelatin plates are as readily differentiable even at first sight as it is possible for bacilli to be, and that in rabbits and guinea-pigs infection with the bacillus choleræ suis produces a large number of foci of coagulation necrosis (dirty whitish spots), which are absolutely specific for the micro-organism described by Salmon, while they are never noted in animals inoculated with the bacillus icteroides In regard to this matter Reed and Carroll make the following observation: "The lesions produced in rabbits and guinea pigs inoculated with bacillus icteroides and the hog-cholera bacillus are practically the same, the most constant change consisting of multiple necroses in the liver. Sanarelli does not appear to have made any mention of this most striking lesion."

I am very much surprised myself that Reed and Carroll should have found this lesion and should have betrayed seemingly good faith in describing it so carefully, without realizing that the lesion is entirely specific to hog cholera and limited to that affection and is completely unknown in infections with bacillus icteroides. I, myself, who certainly possess an extensive experience in the matter, having made thousands of autopsies on rabbits and guinea-pigs that had died from infection with bacillus icteroides, have never seen the necrotic patches of the liver they describe, and my experience is confirmed by many observers who have down to the present time repeated and controlled my experiments in so many different countries.

I have every reason to think, then, that Drs. Reed and Carroll have fallen victims to some deplorable neglect of technical precautions in the laboratory, and all the more am I compelled to think so because I gather from their experiments that the results observed after inoculations of the bacillus icteroides into other animals, by no means correspond with those described as occurring in the rabbit and guinea-pig.

As a matter of fact among other things Drs. Reed and Carroll did not succeed in reproducing the acute steatosis, fatty degeneration of the liver in dogs that was always so prominent a feature in my own observations, as well as those of Foa,[1] Belfanti and Zaoni,[2] De La Cerda,[3] Cesaris Demel,[4] Della Rovere,[5] Mendoza,[6] Ramos,[7] Bruschettini,[8] and others. This acute fatty degeneration of the liver is very characteristic and is produced much more rapidly and with much more intensity than fatty degeneration following phosphorus poisoning.

In the presence of hiatuses of observation and inexactness in detail in their experiments so great as these I find it impossible to give any serious consideration to the strange position taken by Drs. Reed and Carroll. It is evident that their conclusion has no other significance than that a gross and deplorable error was made in their laboratory and that somehow the cultures of the two micro organisms being experimented with got mixed for want of sufficient attention.

The bizarre effect of the hypothesis that they advanced is enhanced by the startling consideration that Drs. Reed and Carroll announce as a convincing element in the analogy between the bacillus icteroides and the bacillus choleræ suis, that both of these micro-organisms resist extremely low temperatures very well. As if it were not well known that all bacteria without distinction are endowed with the faculty of resisting low temperatures, or as if any one had ever succeeded in finding for bacteria the limits beyond which they would not stand refrigeration and as if this quality of resistance to low temperatures were to be set down as one of the characteristics of bacteria by which they might be recognized!

But this discussion as to the resistance of the bacillus icteroides to cold is not new. It was inaugurated by another bacteriologist, Dr. Novy, who, in a long article made up to a greater degree of

critical and philosophical considerations than of clinical or anatomical or experimental observations has attempted to show indirectly that the bacillus icteroides *could* not be the cause of yellow fever.[1]

It seems worth the while for me to transcribe the last period of this article because it gives an opportunity to judge at once of the whole system of reasoning to which the author abandons himself with an aggressive spirit which it is very hard to explain.

"This last experiment (exposure to cold) may be considered as a crucial test of the relation of the Sanarelli bacillus to yellow fever. Freezing for three days at a temperature below — 10° C. had absolutely no effect on the virulence of this organism. As pointed out above, epidemics of yellow fever are promptly brought to an end by a sharp frost. In other words, the microbes of yellow fever are exceedingly sensitive to cold. This certainly cannot be said to be the case with the bacillus isolated by Sanarelli. This organism in its behavior to cold again shows that it is related to the colon-typhoid group of micro-organisms. If, therefore, the Sanarelli bacillus were the cause of yellow fever we would expect to find this disease like typhoid fever distributed over the length and breadth of the American continent regardless of climatic conditions."

Now in order to imagine seriously this strange supposition in actual experience requires a mind absolutely guiltless of even elementary knowledge of epidemiology, not only as regards yellow fever but also with regard to the other serious epidemic diseases, which have in general their ordinary foci of greatest activity and points of maximal development in warm countries.

Not only yellow fever, but all the endemic diseases (malaria, etc.) and the epidemic diseases (cholera, pest, typhoid fever, dysentery, and the like) diminish in virulence and often almost disappear with the advance of the cold. But this phenomenon has absolutely no relation to resistance of their respective specific microbic causes to cold. The reason for their diminution during the winter is simply that while exposed to persistent low temperatures all pathogenic microbes without exception cease to multiply. But their cessation of reduplication by no means signifies that they have lost their vitality or virulence, since the return of warmer weather is almost invariably accompanied by renewed outbreaks of the epidemics.

A very instructive example of this is furnished by Asiatic cholera, which is a striking type of a disease that practically always disappears with the first cold weather. In spite of this, however, the vibrio of cholera has been known to resist exposure for 120 days to the severest cold, the minimal temperature of which was 31.8° C., and that, too, despite the fact that it was allowed to thaw out several times[1]. The bacillus of pest (bubonic plague) also has resisted for more than 40 days a temperature of 20°[2]; the bacillus of typhoid fever was found alive even after 103 days of exposure to a temperature of 10°[3], etc., etc.

It is no great matter for wonder then if Dr. Novy found the bacillus icteroides neither dead nor lessened in virulence after but 3 days of exposure to the cold of his window-sill. How can he conclude, besides, from this extremely defective experiment, that the bacillus icteroides comports itself when subjected to cold like a number of the colon-typhoid group, especially as there can not be found in contemporary scientific literature any reliable data as to the limits of resistance of these microbes when exposed to low temperatures? The comportment of the colon and typhoid bacilli in the presence of cold is entirely unknown in bacteriology and there is not the slightest reason to think that it is any different from that of any other microbe.

Is it possible that Dr. Novy is not aware that during the old epidemics of yellow fever in Philadelphia and Baltimore, precisely during the months of November and December, while the temperature was at times below zero, more than 100 persons a week were being carried off by the disease?[4] Or can it be that Dr. Novy does not know of examples of vessels infected with yellow fever, in which the germ of the disease was not destroyed despite the fact that they had been frozen up in Arctic ice for months? Or can Dr. Novy mention a single specific pathogenic germ that is not capable of enduring low temperatures?

After that it seems to me superfluous to defend myself against the remainder of the article cited. For the greater part it is made up of a series, as long as it is useless, of elementary laboratory exercises, executed with the idea of demonstrating the morphological and cultural differences and analogies between the bacillus icteroides, the bacillus of typhoid and Havelberg's bacillus, the last of these as we learn from a note, being nothing else than the common colon bacillus.

After the detailed descriptions given by myself and many other well-known bacteriologists of the morphological characteristics of my bacillus icteroides and the directions for its bacteriological diagnosis, I think that Dr. Novy might well have spared himself the pains of devoting himself to a work so little

capable of supporting the thesis which he has chosen and seems resolved to maintain at any price. This thesis is naturally that of Dr. Sternberg, and consists in declaring *a priori*, that the bacillus icteroides possesses absolutely no etiological significance in yellow fever. It matters not that this declaration is unsupported by even the slightest clinical observation, that not a single autopsy is brought forward to substantiate it, and that it has not been deemed necessary to institute the numerous and carefully conducted experiments upon animals which are usually supposed to give weight to an opinion in bacteriology!

It is easy to understand, then, that in order to be able to write his criticism without having recourse to these experimental elements Dr. Novy has been compelled to adopt a system of *a priori* criticism that fortunately has been banished definitively from the domain of the biological sciences. I have presented a fair and eloquent example of his critical method, but I feel compelled to deplore the utter levity and the want of anything like even elementary competency tor bacteriological criticism that characterizes the method Dr. Novy has employed in setting forth his objections to my discovery.

For example, he makes a great deal of the so-called laws of Koch, and insists that since I have not been able to isolate the bacillus icteroides in every case of yellow fever, that therefore, it cannot be the specific cause of the disease. He fails entirely to take account of the fact that I explained at length the reasons for these defective results in my original work and that I have considered them from the beginning as not final. I have I think demonstrated that this partial failure was due to exceptional circumstances in the investigation.

As a matter of fact I hope that by this time Dr. Novy has changed his opinion in this regard, for he must know that Drs. Archinard and Woodson[1] working in New Orleans, have succeeded in isolating the bacillus icteroides in more than 80 per cent. of their cases of yellow fever and he is surely aware that Dr. Geddings isolated it in 79 cases, 93 per cent. of those he had under observation. The official commission sent by the President of the United States to study yellow fever after long studies of the disease in Louisiana, Mississippi, and Cuba report[2] that they were able to isolate the bacillus icteroides in practically every case, while they never found it in an individual who had died from any other cause than yellow fever.

Dr. Novy criticizes the results of my experiments on dogs, but he adduces no experiments of his own to sustain his critical statements. He really shows a very complete ignorance of the present scientific literature of yellow fever, for it would require but a very superficial reading of the literature of the subject to know that the infectious and toxic symptoms and lesions produced by the bacillus icteroides and its toxins, reproduce all the specific marks of yellow fever in the human being. They especially produce that profound and characteristic fatty degeneration of the liver which experimentally we are not always able to produce even by phosphorus poisoning. It is even worse than the hepatic steatosis that follows phosphorus and it is absolutely characteristic of yellow fever.

Dr. Novy without further ado denies the absolute specificity of this fatty degeneration of the liver and asserts gratuitously that it may be produced by other microbes. He brings forward, however, no experimental observations to support this position and seems to be ignorant of the fact that I have published a series of comparative researches on this subject of the production of fatty degeneration in animals as effected by various pathogenic microbes. My method consisted in an accurate determination by means of chemical analysis of the amount of fatty substances to be found in the viscera of various animals after infection. I succeeded in demonstrating that the bacillus icteroides is far and away ahead of all other pathogenic micro-organisms in producing steatosis in the animal organism[1].

Dr. Novy demonstrates further and successfully that the toxins produced by the bacillus icteroides are not as powerful as those formed by the bacillus of tetanus or diphtheria. I have never even distantly hinted, however, that they were and if my eminent critic wishes to make it understood thereby that because of its lesser toxicity my bacillus cannot be accepted as the cause of yellow fever, then I must say that he holds an opinion entirely personal and peculiar to himself with regard to the pathology of the infectious diseases in general.

According to his way of looking at it there should be but two microbes capable of killing the animal organism by means of their soluble toxins, namely, those of diphtheria and tetanus! Are not typhoid fever, cholera, pneumonia, streptococcemia, tuberculosis, etc., also infective diseases characterized by the presence of a powerful, soluble poison elaborated

[1] Average quantity of fatty substances contained in the liver of animals: (Average results of a number of analyses.) Normal dogs (as controls) 6.54 per cent. of the dried residue. Dogs after infection with the cholera vibrio 9.44 per cent. of dried residue. Dogs after infection with colon bacillus 10.60 per cent. dried residue. Dogs after infection with bacillus pyocyaneus 11.22 per cent. dried residue. Dogs after infection with diphtheria 14.65 per cent. dried residue. Dogs after infection with bacillus icteroides, 22.69 per cent. dried residue.—*Centralbl. für Bakteriologie*, No. 10, p. 382, 1898.

in their respective specific germs, even though their toxins may not be as rapidly fatal as those of diphtheria and tetanus?

If Dr. Novy desires, however, to have a more exact notion of the toxic powers of the bacillus icteroides, I should advise him to read an excellent article on the subject, the result of actual experiments by Belfante and Zanani[1] in which he will find an amount of interesting material that will supply certain defects in his present information on the subject.

After this I shall occupy myself only briefly with a most original declaration by Dr. Novy, who asserts that "from the above it is evident that Sanarelli's bacillus produces in experimental animals a disease not unlike that following infection with the bacillus coli communis."[2] This is equivalent to impugning either the good faith or the good judgment not only of myself, but of a now numerous following of distinguished bacteriologists who have announced their belief that we have in the bacillus icteroides a pathogenic microbe distinct from the external colon bacillus, which constitutes the great coefficient of ordinary errors in bacteriology and is without doubt the greatest crux of bacteriological investigations, whenever intestinal contents enter, however remotely, into the subject to be studied.

Now it was precisely because of this and to make the matter clear to inexpert or impractical bacteriologists, that I take the trouble to insist at such length on the fundamental characteristics which differentiate beyond peradventure of error the bacillus coli communis from the bacillus icteroides.

The last part of Dr. Novy's article is taken up with the subject of vaccination, and with the agglutinative power of various serums. But even here there is a lamentable confusion of opinions and of experiments which results in an incomprehensible muddle. For example, the author did not succeed in obtaining a serum with sufficiently high preventive powers from a horse that he thought he had vaccinated thoroughly after five months of injections. Annoyed by this failure he proceeds to cry out without more ado that the bacillus icteroides is not capable of producing a soluble toxin.

It is evident that he is not aware of the investigations on this subject[3] published by one of our most eminent experimenters,[4] and in which he demonstrated beyond all doubt the antitoxic value and the preventive and curative powers of a serum obtained from horses properly vaccinated. The serums are effective against the bacillus icteroides and its toxins.

Finally, Dr. Novy experimented with the bacillus icteroides and serums derived from horses that had been vaccinated against pest and against the colon and tetanus bacilli. He found that all of these serums indiscriminately caused agglutination to occur in cultures of the bacillus icteroides and concluded from this with what we may call, I think under the circumstances, his habitual unreflecting precipitancy, that therefore this phenomenon was of absolutely no importance as regards the demonstration of specificity.

But it is evident that Dr. Novy has been deceived once more in this for want of taking proper account of the dilution of his serums, for it is well known that these researches in agglutination have no value unless they are practised comparatively and with dilutions of serum always at least 1–40.

I consider it scarcely worth the while at this late day to call Dr. Novy's attention to the results obtained after long and serious investigation of the subject of the serum diagnosis of yellow fever in New Orleans, by P. E. Orchinard, R. S. Woodson, J. Archinard,[1] and O. L. Pothier.[2] They demonstrated indisputably that the serum of yellow-fever patients, of convalescents from the disease, and of those fully recovered, was endowed with an agglutinative power entirely specific for the bacillus icteroides, which was not noted in the case of other bacilli if the dilution was sufficient.

The last of this long series of inexactitudes is especially laughable. Dr. Novy declares that the negative bacteriological investigations, together with the facts observed during epidemics of yellow fever, justify the conclusion that the specific microbic cause of the disease, like those of smallpox, measles, hydrophobia, etc., belongs to a group of micro-organisms that are invisible to the microscope!

I find this a very convenient way of looking at the subject especially for such as Dr. Novy, who have neither the time nor the wish to undertake the voyage to Cuba in order to see a yellow-fever patient or two, or to make a few, or at least some modest bacteriological investigations in the home of the disease. I cannot admit, however, that the science of epidemiology gains much from this method of argumentation borrowed from metaphysical sources.

On the contrary, the ready propagation of the disease, the exceptional longevity of its pathogenic agent whatever it may be, its rapid acclimatization in localities that cannot at first offer it an especially suitable means of nutrition, its resistance to desiccation and various other considerations which can be gathered without difficulty from the known epidem-

iology of the disease might easily have led one to believe that even before my discovery the specific cause of yellow fever, whatever might be its nature, was not very different from the ordinary type of pathogenic microbes that are known, since its habits and manner of life are regulated by the same conditions, ruled by the same laws. As a consequence its isolation in pure culture promised with the varied nutritive materials that we have at our command now to be only a question of time, of of ability, especially of sufficient preparation and of tenacious persistence.

My preceding and rather well-known researches on the etiology and pathogenesis of typhoid fever[1] of cholera,[2] to which I devoted a good deal of not unfruitful time and labor, put me in the position certainly of having sufficient preparation even for the difficult bacteriological problem presented by yellow fever.

My pathogenetic criteria had been developed especially by the work on typhoid fever[3] and this contributed not a little to orient me at once even as to the probable mechanism of the infection by yellow fever. It pointed out very happily the direct path that had to be followed in order to demonstrate the so-much-sought-for specific microbe of that dread disease.

I am inclined to doubt if those who find it so easy to criticise are in a position to treat the bacteriological and pathogenetic questions of the infectious diseases with as much experience and authority, for these can only be acquired after many years of practical study at the bedside of the sick, in the autopsy-room and in the laboratory of comparative experimental pathology.

TUBERCULOSIS OF THE KIDNEY AS AN INDICATION FOR NEPHRECTOMY.[4]

BY EDWARD REYNOLDS, M.D.,
OF BOSTON, MASS.

My text in this short paper is that tuberculosis of the kidney is not always the hopeless and destructive bilateral complication of other tuberculoses, which some observers still believe that it almost invariably is, but that some recent experiences of my own have led me to believe that it is not infrequently unilateral, and primary in that one kidney, and that in such cases its clinical course is widely different from that usually ascribed to it. I believe that when it is bilateral, or even when it occurs as a unilateral disease in broken down or profoundly tuberculous constitutions, it is a rapid and hopeless affection and that such cases are unfit for surgical treatment, but that when it is primary and unilateral and occurs in fairly resistant women it is a slow and insidious disease, which is not infrequent in the community, which is often characterized during many years by but trifling symptoms and is then readily curable, but is usually unrecognized until after it has become incurable. I believe, in short, that in some instances, this disease is today fulfiling the rôle, which was so long enacted by chronic appendicitis and tubal pregnancy, and that with further study it will yield us another and wide extension of our usefulness. I believe that success in the operative treatment of this affection rests upon the selection of cases; upon the selection for operation of those patients who remain for years in good general condition; in whom the disease is slow and chronic and, therefore, unfortunately, obscure and easily overlooked; but the main object of my paper is to urge upon all the mere fact of its existence. In support of this view I wish to bring before you not theoretical considerations, but the somewhat suggestive details of the cases which I have myself observed, together with a few words as to the methods of diagnosis and treatment which I have found useful.

The first point which strikes me as of interest in my cases is that all the patients were brought to me by their physicians for the relief of urinary discomforts, and as afflicted with moderate debility, but not in any instance for the cure of an important disease, the symptoms in all cases consisting of a rather deteriorated condition of health, and habitual, though sometimes transient, attacks of urinary discomfort. The second is that three out of four of the patients had tuberculous family histories. The third, and one of the most striking features, is the long duration of the illness in some of the patients before it was brought to the notice of a specialist, the patient whose kidney was least advanced in the disease having a history of eight-years' duration, while another whose kidney showed only the presence of two small abscesses of the size of a pigeon's egg had a history of twenty years of suffering. Two patients had suffered from repeated attacks of somewhat profuse hematuria; none of the others showed any symptoms which could be differentiated by the study of the history from those of an inflammatory affection of one kidney.

Briefly, the history of all except the hematuric cases, consists only of long-continued debility, with frequency and discomfort in micturition, and sometimes pain and tenderness referable to one kidney or

[4] Read at the twenty-fourth annual meeting of the American Gynecological Society, held at Philadelphia, May 23, 24, and 25, 1899.

ureter. Curiously enough the pain and tenderness, in this as in many other unilateral renal affections, is not infrequently referred to the sound side, where it may even be intense. One patient had a history which rendered the existence of previous but transitory pulmonary tuberculosis likely.

The diagnostic lesson which I have learned not only from these cases, but from a considerably larger experience with other affections of the urinary organs is that the most which we can gather from a history which consists only of long-continued debility and urinary symptoms, is that in such cases the debility is usually though not always the product of the urinary disease; that the nature of the urinary difficulty can only be determined by a physical examination of the urinary organs; and, finally, that the physical signs of even somewhat advanced urinary tuberculosis may be at times, and especially in its quiescent periods, so slight that the disease will be missed by any but inoculation tests. I am not sure that it may not sometimes be missed at such periods even by these delicate reactions, although out of a considerable number of negative inoculations I have so far had none in which the subsequent operation or course of the disease failed to show the patient to be clear of tuberculosis.

The methods which I use are careful palpation over both kidneys and the course of both ureters including their vesical ends; a visual inspection of the bladder; in the absence of definite lesions of this viscus, a catheterization of the ureters, and the submission of the separated urines not only to a microscopical examination by an expert, including a careful search of stained specimens for the tubercle bacillus, but also to the injection of a portion of each sediment into a separate guinea-pig. The importance of adding the last method of examination to our tests is, I think, shown especially well in the fourth case on my list, in which repeated examinations for tubercle bacilli by Dr. J. B. Ogden of the Urinary Laboratory of the Harvard Medical School, failed to show their presence, though made while the bladder was the seat of ulceration, and although the guinea pig inoculated with the urine of the affected kidney promptly became infected with the disease, while a pathological examination of the specimen after nephrectomy showed the presence of two tubercular abscesses, which communicated with the pelvis of the kidney. In the absence of hematuria the microscopic examination of the urinary sediments of the divided urines may even fail to show any disease, especially on a single examination only; since a sediment which at one time contains a large amount of pus, may at other times (and probably for long periods) show only scattered leucocytes and but little else of significance, yet in my second case an inoculation was positive in just such a urine and the kidney was found to be tuberculous.

As regards treatment, I have subjected the three patients upon whom I have already operated to simple nephrectomy, on the ground that even if there were a tubercular infection of the portion of the ureter which was left behind it would surely disappear under the retrograding processes which a ureter necessarily goes through after its kidney has been removed, and in the two cases in which eleven and eighteen months have already elapsed since the operation, the restoration of the patients to continued and perfect health has shown the justice of this view, while the rapid improvement of the third in the short time which has elapsed since the operation makes a similar result seem probable, but the persistence in one of these cases, and in several other of my nephrectomies, of considerable urinary suffering during the convalescence, which I have attributed to the distention of the stump of the ureter by retained secretions, with the appearance in one case, late in the convalescence, of suppuration which seemed attributable to infection from the stump of the ureter, together with the fact that in a case which I saw in consultation after nephrectomy had been performed, it was necessary to remove the ureter for continued suppuration, have led me to propose for the future to treat such cases by nephro-ureterectomy. The rapid and complete restoration of health, with gain of weight and healthy color, which these patients have exhibited after operation, together with the easy vicarious assumption of the whole function of elimination by the remaining kidney have made me feel that nephrectomy is a wholly justifiable operation for proper cases of unilateral tuberculosis of the kidney; and I may add my belief that the enormous mortality which has in the past attended this operation has been due in part to imperfect diagnosis and selection of cases, and in part to the fact that it has usually been reserved for a last resort, in cases which are already in a condition which renders any surgical operation unpromising. I believe that if it is applied to women who are in fair condition, its mortality will be very small; to say nothing of the fact that we may fairly believe that the improved technic which always follows the frequent performance of an operation will probably in time reduce the mortality of this operation as it has that of hysterectomy.

Two of my cases have already been reported in detail; the others will be as soon as a sufficient time has elapsed since the operations, but a few particulars of them may properly be included here.

The first patient, Mrs. R., seen with Dr. Hedenberg of Medford, Mass., had been subject to attacks of

urinary frequency for five years. She had had some pain and tenderness over the course of the left ureter for about one year, and though not confined to her room except at the time of her attacks had been in poor general health during the whole five years. At the time I first saw her, her urine had for some weeks contained considerable quantities of pus, and she had been urinating about every twenty minutes through the daytime and some five times at night. Her bladder was the seat of general inflammation, there was marked redness and erosion about the left ureteral orifice, and several polypi, apparently secondary, about the internal orifice of the urethra. Local treatment of the bladder entirely relieved her symptoms within a few weeks and disposed of all the vesical lesions except the erosions about the left ureter, tne vesical end of which was enlarged and hardened to the touch, but this relief was not permanent, in fact comfort was only maintained by almost continuous treatment of the bladder, and her general health was manifestly running down.

An incision down to the left kidney December 3, 1897, showed it to be much smaller than normal and on removal it was found to consist of but little more than a shell filled with cheesy pus. On section its tissues were found to be full of tubercle bacilli, though a previous examination of the urine at a time when it was full of pus had failed to detect them. No inoculation test was made. During the year which followed the operation the patient enjoyed perfect urinary comfort, gained greatly in strength, color, and general health, and has remained a wholly well woman ever since (about 18 months). The case was reported in the *St. Paul Medical Journal*, May, 1899.

The second patient, seen with Dr. P. C. Proctor of Gloucester, Mass., had a tubercular family history but had had no such trouble herself. She had been a semi invalid for eight years, her illness dating from an unexplained attack of hematuria. She had had one other similar attack five years later, and I saw her during the third, which lasted for some weeks and was profuse enough to blanche her severely. Her only other symptoms were slight frequency during the hemorrhages and some backache and bearing down during the intervals, but none in the attacks. Her bladder was normal, but blood was oozing from the right ureteral orifice. A search of the ureteral sediment for tubercle bacilli conducted by Dr. Ogden was negative, and in fact the sediment contained practically nothing but the blood, but a guinea-pig inoculated with the sediment of the right kidney developed tuberculosis, while one inoculated from the left side remained well. I removed the kidney on June 24, 1898. All the symptoms were at once relieved, the patient considered herself in perfect health at the end of three months, and has remained so ever since, having regained her normal weight, color, and strength. The pelvis of the kidney contained numerous scattered miliary tubercles. The case was reported in the *Johns Hopkins Hospital Bulletin* for November, 1899.

The third patient was seen with Dr. Edgar Garceau of Roxbury, Mass., after he had performed a nephrectomy. Both family and personal history were clear. The duration of her symptoms before the operation was about one year. She had had pain and tenderness over the situations of the left ureter and kidney, some pain on the left side when lying in bed and pain referred to the neck of the bladder. She had passed urine about forty times during twenty-four hours. There had been no hematuria. There were ulcerations in her bladder which Dr. Garceau had curetted before performing nephrectomy. The diagnosis and indication for operation were founded on an increased size of the kidney on palpation, and on the tubercular appearance of the bladder. An examination of the kidney after its removal showed it to be tubercular. At the time I saw her she was very feeble and greatly emaciated. She had an irregularly elevated temperature, which was apparently due to suppuration about the portion of the ureter which had been left. I thought her too weak for much prospect of success from ureterectomy, but Dr. Garceau courageously removed the ureter, and the patient made a surprisingly uneventful return to entire health and resumption of her work, which condition she maintained for nearly a year, or until a few weeks ago, when some urinary frequency reappeared, and Dr. Garceau informs me that she now has a few ulcerations of the bladder which, however, he hopes to cure by local treatment. This, as is readily seen, was a very unfavorable case, and was moreover, in very unfavorable hygienic surroundings. She has, nevertheless, received much benefit and may yet be cured, as the recurrence of the disease is thought to be limited to the bladder, and I have already had two cases of primary tubercular disease of the bladder in which healing occurred after local cauterization, and both patients have remained well, one for more than a year, and the other for more than three years. This operation was undertaken, however, without bacteriological proof of the soundness of the other kidney, and should therefore, I think, be considered as in a little different class from the other cases reported.

My fourth patient was seen with Dr. A. A. McDonald of Roxbury. Her family history was tuberculous, her personal history good. She had suffered for twenty years with urinary discomforts which

grew worse at intervals but were never wholly absent. For four years she had been subject to acute pain over the left ureter and kidney, and occasional though not very severe left-sided renal colic. At the time I saw her there was no tenderness on either side and neither ureter could be felt on palpation per vaginam. She was then urinating from forty-five to fifty times each night and almost incessantly through the day. Her bladder was studded with tubercular ulcers. I considered the case wholly beyond the reach of radical treatment, but advised Dr. McDonald that I thought he might greatly lessen her suffering by cauterizing the vesical ulcerations with solid nitrate of silver warning him, however, that this would be a very tedious task, and that I was very skeptical of his even reducing the bladder to a normal condition. A guinea-pig inoculated with her bladder urine promptly developed tuberculosis, and I was greatly surprised when the doctor brought her back to me, after three months of most patient and almost continuous treatment, with an entirely normal bladder. On palpation I now found the vesical end of her right ureter to be thickened (it is to be noted that all the symptoms were upon the left side). I then catheterized her ureters and submitted the specimens to Dr. Ogden. No tubercle bacilli were found, but the guinea-pig inoculated from the right side developed the disease, while its fellow inoculated from the left side remained well. The urine from the left side appeared normal with the exception of the fact that it contained a good deal of stringy mucus. This probably accounted for the occasional renal colics, but the appearance of even this slight abnormality on the sound side made me feel very unwilling to operate, and I refused to do so until repeated catheterization of the ureters had yielded uniformly the same results. Then, in view of the facts that there was undoubtedly tuberculous disease in the right kidney, that the physiological action of the left was good, that the woman had gained considerably in health and strength in the four months during which she had waited for the inoculation and other tests, and that the bladder still remained normal, I consented to a nephrectomy on the right side. This was performed on March 8, 1899, and it is too soon to report the result, but it is a striking fact that the left-sided pain was gone when she came out from the influence of ether, and never recurred, and that the urinary frequency is gone, and that she has already gained in general condition. The kidney contained two small tubercular abscesses. In two other cases the diagnosis, though probable, is not yet fully established by the inoculation test and I therefore prefer not to report them.

RETENTION OF THE TESTICLES, WITH REPORT OF CASES.[1]

By L. L. HILL, M.D.,
of Montgomery, Alabama.

It is essential to a thorough understanding of an abnormality that we have a clear comprehension of the normal. This is especially applicable to the subject which I now propose to consider. Anatomists tell us that the testicles in early fetal life are located behind the peritoneum and below the kidneys. About the third month a slender band of unstriped muscular fibers, the gubernaculum testis, is observed, which eventually, in the marvelous process of development, connects the testicle with the bottom of the scrotum. As the fetus elongates the gubernaculum not only does not commensurately lengthen but progressively shortens, necessarily causing descent of the organ into the scrotum. The testicles are found in the scrotum at birth in eighty per cent. of all cases. Of the retarded twenty per cent. only one in a thousand finds permanent lodgment in the inguinal canal or abdomen Professor Keyes reports descents as late as the thirtieth year. Less frequently they stray from the usual path and may be found in the perineum, the most common form of ectopy in man, and the natural position in some of the lower animals, as the pig. Having passed through the femoral ring they reach the thigh, or there may be penopubic ectopy. Those which descend after birth are usually complicated with hernia and when permanently retained are often given to structural degeneration.

The cryptorchid is generally copulative but sterile, losing his spermatogenesis but none of the other attributes of masculinity, the sterility being determined in a given case only by a microscopic examination. Statistics show that the right testicle oftener fails to descend than the left. The chief accredited cause of abdominal retention is intra uterine peritonitis. Non descent may be due to the wearing of a truss or to shortness of the cord. An unusually small external abdominal ring may produce lodgment in the canal. Excessive development of certain fibers of the gubernaculum is responsible for aberrancy.

Having thus briefly considered in a general way some of the features of this interesting subject, I will report three cases that have come under my observation, with the treatment that was adopted.

Case I.—E. B., aged twenty-four years, white, a clerk in a railroad office, applied to me in December, 1895, presenting an enlargement in the right inguinal region which he said had existed since his birth. He complained of an uneasy and disagreeable sensation which was accentuated when the

[1] Read before the Medical Association of the State of Alabama, at Mobile, April 20, 1899.

bowels became constipated and distended with gas. The pain rendered him incapable of properly attending to his duties.

Upon examination I found an undeveloped scrotum and a retained testicle in the inguinal canal complicated with an irreducible bubonocele with which it was inseparably connected. Hernia is one of the most frequent complications of this form of undescended testicle and particularly dangerous on account of proneness to strangulation. Trusses, recommended with large concave pads to prevent an increase of the hernia and protect the testicles, are in the main unsatisfactory. I accordingly advised an operation for the radical cure of hernia and if possible transplantation of the testicle in the scrotum, and if the latter was not found feasible, then a castration. To the partial emasculation he strenuously objected, which from the appearance of the testicle was more a matter of sentiment than anything else. Contrary to my better judgment I yielded to his entreaties and promised not to sacrifice the testicle in case the scrotal transplantation failed, but to try to relieve him of his pain by a conversion of his retentio inguinalis into a retentio iliaca, and absolve him from the jeopardy of a strangulated hernia by radical operation, as much as possible after the method of Bassini. Owing to the shortness of the cord and my inability to carry the testicle to the scrotum even after I had thoroughly divided the musculofibrous funicular sheath it became necessary to do this. I considered the advisability of dissecting the globus major from the testicle and turning the organ upside down, an operation I had seen Mr. John Wood do some years before in London but concluded even this additional lengthening would not carry it to its habitat.

More than three years have elapsed since the operation and the patient has attended daily to his duties and has suffered no inconvenience. Had I seen this patient early in life, when the hernia was probably reducible, I should have used the horseshoe contrivance of Wood and attempted to push the testicle into the scrotum and at the same time restrict the hernia to the abdominal cavity. There are excellent surgeons who, when it is possible, return both hernia and testicle to the peritoneal cavity and apply a truss to keep them there if they are inseparable.

Case II.—E. C., aged twenty-five years, white, consulted me in February, 1896, on account of the absence of the testicles from the sac. I found both testicles retained in the inguinal canals. They seemed to be about one-half their normal size. It was impossible to push them through the external rings. The scrotum was undeveloped and measured transversely only half an inch. Aside from his desire for relief purely on grounds of adornment and development, their exposed position subjected them to frequent traumatism.

I advised an operation, to which he readily consented. Making an incision sufficiently long to well expose the testicle, I applied downward traction to the organ and divided the tissues of the cord transversely, barring the vas, vessels, and nerves. Passing my finger into the lower end of the wound I forced an opening into the scrotum for the retention of the belated testicle. Invaginating the sac, I sewed the testicle to its bottom with catgut. The aponeurosis of the external oblique was next closed with catgut and the external ring was left large enough not to interfere with the circulation of the spermatic vessels. The cord was sutured to the pillars of the external ring and the wound in the skin closed. In dressing the wound I used a compress of antiseptic gauze to aid in keeping the testicle in its correct position. Waiting until the wound had completely healed I repeated the operation on the right side. Since the transplantation the testicles and scrotum have developed to their natural size, and were it not for the scars a former abnormality would not be suspected. In cases of double retention like this only one side should be operated on at a time as I am satisfied the rudimentary scrotum could not have safely held both testes.

Case III.—F. C., about six years of age, son of a physician, was brought to me by his father for the relief of an undescended testicle on the right side. He was very anemic. The father stated that the testicle frequently became enlarged, and very painful and tender to the touch. Sometimes he could get a history of injury, but often he supposed it to be due to the contraction of the abdominal muscles. The child was an epileptic, the seizures coming on whenever there was any disturbance of the testicle and at no other time, and their frequency and severity were proportionate to the amount of irritation. I gave as my opinion that it was a case of reflex epilepsy and that the testicle should be released from its incarceration, preferably by anchoring it in the scrotum but if need be by extirpation. I performed the operation just as in the previous case and had the satisfaction a short time ago of receiving a letter from the father, a very intelligent physician, in which he said that the boy was in good health and that "there had been no return of the nervous symptoms from which he suffered previous to the operation."

There are two features of special interest in this case, the first being that it was a genuine case of reflex epilepsy as shown by immediate cessation of seizures after the operation. The second is that there was a sudden rise of temperature to 106° F., within twelve hours after the operation, at which point it remained for three days with slight variation, and then gradually declined to normal. The wound healed without suppuration. I do not believe the rise of temperature was a so-called post-operative rise, but was incident to an excitation of the thermogenic centers from the source of irritation, the impressionable impulse being transmitted through the sensory nerves.

Professor J. William White of Philadelphia advises the performance of these operations before the age of puberty. His opinion is entitled to serious consideration. To this distinguished surgeon is due

great credit for having elucidated and popularized the means of relief.

THE CHOICE OF DRUGS TO DILATE THE PUPIL.

By EDWARD JACKSON, M.D.,
of Denver, Col.

The influence of certain drugs in producing dilatation of the pupil is so striking and so characteristic that they are mostly grouped under the name mydriatics. The most of these resemble each other closely in all their physiological actions and therapeutic capabilities. Yet several of them differ sufficiently in their influence to render the one or the other distinctly superior in certain cases; and one drug, cocain, differs from the others so completely as to place it quite outside the group of true mydriatics, although it possesses a power of dilating the pupil that is of the highest practical value. Along with their power of producing dilatation of the pupil, mydriasis, these drugs all possess in varying degree the equally useful power of causing paralysis of the ciliary muscle, cycloplegia. In this paper their action as cycloplegics will not be referred to except as cycloplegia may be a valuable adjunct or a distinct disadvantage in their use as dilators of the pupil.

As the basis for choosing the particular drug most appropriate for a particular case, we have their somewhat different physiological actions on the pupil. Ten or twelve minutes after a drop of a solution of atropin, 1 to 120 (4 grains to the ounce), is placed in the conjunctival sac the pupil begins to dilate. The dilatation increases rapidly; the pupil at first reacts well to light, but is less and less affected by illumination as it grows larger. In fifteen or twenty minutes after it begins to dilate the maximum size of the pupil that can be produced by atropin is reached, and it becomes quite fixed, failing to respond to any of the forms of stimulation that produce reactions in the normal pupil. For about two days this condition remains unchanged. Then the pupil very slowly becomes smaller, and at the same time its reactions gradually return, until at ten or fifteen days after the application of the drug it has again become normal. Repeated instillations of such solutions prolong to any desired extent the period of complete dilatation, and recovery may be slower. I have seen three full weeks elapse between the last instillation and complete recovery.

Reference is here made to complete recovery, the period of which can only be accurately determined when the drug is used in but one eye, the other being kept normal as a standard of comparison. Often in six or eight days recovery may be so far advanced that no great inconvenience is experienced from the remaining dilatation, and after that the recovery is so very gradual, that some patients still think it not complete long after every trace of the action of the drug has passed away.

Dilatation of the pupil by atropin is accompanied by paralysis of the ciliary muscle, and suspension of the power of accommodation. This begins with dilatation, reaches the maximum in one or two hours, remains complete for about two days, and then slowly passes off as the pupil contracts. With smaller doses of atropin the period of complete dilatation is shortened. A drop of a solution of 1 to 2000 does not produce complete dilatation and fixity of the pupil; and the return to normal will occur in eight or ten days. Of a solution of 1 to 500,000 a single small drop, containing less than one-millionth of a grain of atropin, will produce a perceptible enlargement of the pupil lasting from thirty-six to forty-eight hours.

The actions of the other natural mydriatic alkaloids, daturin, duboisin, and scopolamin are almost identical, and closely resemble that of atropin. They are 2 or 2½ times as strong as atropin, so that used in solution of ½ or ⅔ the strength they produce an equal effect. Recovery from their effects does not require so long as recovery from the effects of atropin. After complete dilatation by one of these drugs the pupil will return to normal in eight or ten days. They also cause complete paralysis of accommodation.

The artificial alkaloid homatropin differs essentially from any of the above in being much weaker in action, and in having a shorter period of recovery. A solution of 1 to 50 is required to produce complete dilatation and fixity of the pupil, and a single instillation of this does not produce complete paralysis of accommodation Recovery is generally complete in two or three days. I have seen it complete in twenty-four hours, but in one reported case the period of its influence lasted longer than five days. Euphthalmin, an artificial alkaloid recently brought forward, is weaker than homatropin, and gives slightly greater dilatation of the pupils as compared with the diminution of accommodation that it produces. One instillation of a solution of 1 to 20 produces almost maximum dilatation, but not fixity of the pupil, and recovery is complete in about twenty-four hours.

In contrast with all the above is the action of cocain. It never produces fixity of the pupil. After repeated instillations of strong solutions the pupil continues to contract on exposure to strong light, and with convergence, yet even a single instillation of a solution of moderate strength will cause with feeble illumination a wider dilatation of

the pupil than can be obtained by any application of atropin, or the stronger mydriatics. Dilatation produced by cocain passes away in about twelve hours, and its effect on the accommodation is very slight. The superiority of cocain is most marked in elderly persons, in whom the other mydriatics produce only imperfect dilatation of the pupil. The influence of cocain is well shown by its effect in enlarging the pupil, when fully dilated by one of the stronger mydriatics.

Bearing in mind the special characteristics of the different mydriatics, let us consider which will best meet the needs of each particular condition, in which the use of a mydriatic is indicated. To dilate the pupil for ophthalmoscopic examination the indication is to dilate it quickly and widely in the dark room for as short a time as possible and to cause the least inconvenience and impairment of vision afterward. This is particularly the case when there is reason to suspect some progressive lesion causing the impairment of central vision, as albuminuric retinitis, or retrobulbar neuritis with central scotoma. It has repeatedly happened to me to meet a patient suffering from one of these diseases in whom for purposes of examination the pupil has been dilated by one of the slower mydriatics. The mydriatic caused immediate impairment of vision, and by the time the mydriatic influence had imperceptibly passed away the original disease had caused an impairment of vision which replaced that produced by the drug. It has usually been impossible to convince such a patient that his eyes have not been permanently damaged by the drops that were put in them. On the other hand, a mydriatic like cocain or a mixture of cocain and homatropin, causes comparatively little interference with vision at any time, and its effect passes off so rapidly that the patient realizes that he has recovered from it before the more permanent loss of vision by disease has progressed so far as to be noticeable.

Then, too, the risk of causing an outbreak of glaucoma by the use of a mydriatic must be considered in every case in which there is impairment of vision and difficulty in making an ophthalmoscopic examination The liability to glaucoma is not confined to any one period of life. It is greater after middle age, but the disease may arise during childhood. From much that is written on the subject one might think that a mydriatic could not cause or aggravate glaucoma in any case until the patient was forty to forty-five years old; and that then every eye became liable to a glaucomatous outbreak from the use of a mydriatic. As a matter of fact no use of mydriatics at any time of life can produce glaucoma in one eye in five hundred; it is only a glaucomatous eye that the mydriatic can so affect. But of the two cases in which I have seen a glaucomatous attack thus produced one was that of a woman only twenty-five years old. Frank Fisher reports a case in which atropin provoked an attack in a girl twelve years old. J. B. Story reports cases occurring at thirteen and eighteen years. S. C. Ayres reports a case in a girl of sixteen and cites eighteen other cases of glaucoma occurring under the age of twenty.

When, on any account, there is reason to suspect glaucoma, the only mydriatic free from liability to produce an attack is cocain. Every new mydriatic has been brought forward with a claim that it was less likely to cause glaucoma than its predecessors, but when given a sufficient trial the claim has in each case been proven false. The only exception has been when the dilatation of the pupil it produced did not last long enough to establish a condition of high tension. The mydriatics cause glaucoma by thickening of the iris periphery, when the whole substance of the iris is gathered into a ring in the region of its ciliary attachment.

All mydriatics which act by paralyzing the sphincter of the pupil produce such a thickening of the iris periphery, with liability to cause blocking of the filtration angle of the anterior chamber and increase intra-ocular tension. Cocain, on the other hand, causes dilatation of the pupil chiefly or wholly through shrinkage of the iris mass by contraction of its vessels, and therefore it has little or no tendency to cause blocking of the filtration angle and a glaucomatous attack. Free applications of it often reduce very markedly the tension of the normal eyeball; and it is of practical value in connection with myotics in reducing the intra-ocular tension during an attack of acute glaucoma.

The diagnosis of glaucoma by the production of an acute attack may be justifiable in some doubtful cases after proper explanations have been made to the patient. For this purpose homatropin is to be used. If it produces an attack the dilatation of the pupil it causes and the consequent increase of intra-ocular tension can be cut short by the use of eserin.

Dilatation of the pupil for accurate measurement of refraction may be needful in old persons with small pupils, quite apart from any need of paralyzing the ciliary muscle. In the trial with lenses the stenopeic effect of the small pupil may be such that the patient will find it very difficult or impossible to choose between different lenses held before the eye. I have seen a patient whose emmetropic eyes were quite devoid of accommodation read thirteen-inch type at from ten to thirteen inches simply because the smallness of his pupils prevented blurring from

imperfect focussing. In such a patient it is quite impossible to make any accurate determination with trial lenses without dilating the pupil. If the pupil in the dark room be less than 3 mm. in diameter the application of the shadow-test also becomes difficult or impossible. To dilate the pupil for this purpose cocain or the combination of cocain and homatropin is to be preferred. To dilate the pupil for examination by oblique illumination when disease or injury is suspected in the lens or anterior vitreous we wish a preparation that will give the widest pupil even under rather strong illumination. This will be a combination of cocain with one of the other mydriatics. Homatropin should be used if the dilatation is only desired during examination; or one of the slower mydriatics may be used with the cocain if the eye is subsequently to be kept under its influence.

In central corneal opacity or partial cataract, either polar or nuclear, we sometimes find that the patient sees better in a dim light because the enlarged pupil then permits the light to enter through the clearer portions of the cornea and lens. In such cases if just sufficient dilatation of the pupil can be obtained when the pupil is exposed to the stronger light vision can be materially improved. For this use cocain is quite unsuitable. Atropin is especially indicated both because of the comparative fixity it gives to the pupil, holding it at about the same diameter whether the light be bright or dim, and because of the persistence of its action, which keeps the conditions of vision comparatively constant without the necessity of frequent applications. The exact strength and frequency of application that will give the best result must be obtained by observation of the particular case, noting the extent and distribution of the opacity, the length of time after the application of the mydriatic, and the size of the pupil when the most satisfactory vision is obtained. The strength of solution required will always be much less than that commonly used to paralyze the accommodation. A solution of 1 to 2000, or 1 grain to 4 fluid-ounces, is a good strength to begin with. This may be instilled once every two or three days, preferably at bedtime, so that the most rapid changes produced by it may be past before the eyes are brought into use again next day.

For certain operations dilatation of the pupil is an aid or an important condition of success, as for the delivery of the lens in the simple extraction of cataract, or the division of secondary cataract. As soon as the anterior chamber is opened and the aqueous begins to escape the pupil contracts. This contraction is less and slower when the pupil has been dilated with cocain than when it is only under the influence of a "stronger" mydriatic. It should be remembered, however, that strong light overcomes the influence of cocain on the pupil, and advantage should be taken of the dilatation secured by excluding light from the other eye.

Suspected iritis is revealed or excluded by dilatation of the pupil. When there is much doubt as to participation of the iris in an inflammation one of the brief mydriatics, as homatropin or euphthalmin, should be tried first, and only when the iritis has been demonstrated in this way need the slower mydriatic be employed.

Dilatation of the pupil in actual iritis is of the greatest practical importance and presents especial difficulties. The iris is swollen by dilatation of its vessels, its movements are hampered by the deposit of exudate in its substance, and later by the plastic adhesions that bind it to the anterior capsule of the lens, and the general congestion and fulness of the tissue greatly interferes with the absorption of the drug employed. Under these conditions the action of the mydriatic may be greatly aided by such measures as local bleeding from the temple to lessen the fulness of the vessels and the internal administration of mercury to influence the tendencies of the exudates.

But there are also clear indications as to the particular mydriatic drug. The small amount taken up into the inflamed tissues renders imperative the use of strong solutions of those drugs which will in small quantity produce the most decided and lasting effects. Atropin and hyoscyamin or its equivalents, in solutions of 1 to 60 or even stronger, must be placed directly on the cornea where the largest quantity will pass through it to influence the iris, and these must often be supplemented by the use of cocain, also in strong solution. The tendency of the stronger mydriatics to cause constitutional symptoms, or in cases of rare idiosyncrasy to set up severe inflammation of the conjunctiva and lids, is the essential check upon the free employment of these drugs. Paralysis of accommodation is here an important aid in combating the intra-ocular inflammation and complete giving up of eye-work a condition of the best recovery.

After paralysis of the pupillary sphincter has been obtained it is at least doubtful if mydriatics like atropin can do much more to secure the breaking loose of adhesions. It has long been taught that these drugs also stimulate dilator fibers of the iris, but the behavior of the normal pupil under them, scarcely supports the view of an active dilatation through stimulation. Of the active retractive influence of cocain, however, there can be little question,

and experience seems to show that the retractile force increases with the dose of the drug which gains entrance to the tissues. Still, cocain is not a drug to be freely prescribed, even in connection with atropin, in the treatment of iritis. It should rather be used by the physician himself in his mydriatic attacks upon the inflamed iris so that its effects can be closely watched.

The combination of cocain with homatropin and other mydriatics has been mentioned. The weak point of cocain used alone is its unfavorable influence on the cornea. The liability to cause serious impairment of the corneal nutrition is the reason for not prescribing it to be used by the patient. Strong solutions cause drying and irregularity of the corneal surface and irregular astigmatism. This may greatly interfere with the ophthalmoscopic examination or the shadow-test, and by impairing acuteness of vision may quite nullify the benefit of dilatation of the pupil for the tests with lenses. On the other hand homatropin interferes more with vision by paresis of accommodation and dazzling when in a strong light and entails a longer period of waiting for recovery. By combining the two the same dilatation of the pupil for practical purposes can be obtained by the use of much weaker solutions and the unfavorable influences of both be eliminated. For simple dilatation of the pupil of the normal eye I have found the following solution most satisfactory:

Homatropin hydrobromate . .	gr. i
Cocain hydrochlorate . . .	gr. ii
Distilled water	f ʒ i.

M.

A single drop of this is to be placed on the upper margin of the cornea. Its maximum effect is produced in about one hour. Recovery from its effects is well advanced in six hours and practically complete in twelve. It causes no irregular astigmatism, but slight impairment of accommodation, and permits a good deal of contraction of the pupil in strong sunlight. Euphthalmin and cocain, each one per cent., in distilled water, may be employed for the same purpose.

THERAPEUTIC NOTES.

Salicylic Acid for Furunculosis.—Philipson (*Deut. Med. Woch.*, May 4, 1899) advises the application of a plaster containing 50 per cent. of salicylic acid in the treatment of a well formed boil. This should be changed four or five times a day and the narcotic process will be much hastened. When the core is eliminated, treatment which favors granulation may be begun. Minute furuncles are arrested by the application three times a day of pure alcohol, or alcohol containing 5 per cent. of tincture of benzoin. Larger furuncles may be washed with alcohol containing 2 per cent. of salicylic acid, all washing with water and soap being omitted meanwhile. In generalized furunculosis the parts should receive a warm bath daily and then be rubbed with vaseiin containing 2.5 per cent. of salicylic acid.

Treatment of Chronic Otitis Media.—Lewy (*Therap. Monatshefte*, May, 1899) draws attention to the remarkable effects which can be produced by trichloracetic acid in chronic suppurations of the middle ear. The applications tend at the same time to close tympanic openings. Regeneration of the tympanum was obtained in the majority of the cases treated. The ear is first cocainized with a 10- or 15-per-cent. solution. A metallic loop upon which a crystal of the acid has been fused is then passed into the chamber and the mucous membrane cauterized by it. The edges of the tympanic opening are treated in like manner. For the latter one application a week will suffice. To obtain the arrest of suppuration in the middle ear it will be necessary to cauterize more frequently. The application is always painful despite the cocain, so that the saturated solution of the acid on a cotton swab is preferred by some to the solid crystal.

Aspirin or Acetyl-Salicylic Acid. — Wohlgemuth (*Therap. Monatshefte*, May, 1899) tested some of the compounds of salicylic acid in order to find one equally effective as salicylate of soda but less irritating. By the action of anhydrous acetic acid on salicylic acid he obtained white crystals of acetyl-salicylic acid, readily soluble in alcohol or ether, and to the extent of one per cent. in lukewarm water. The drug does not decompose in the stomach until it has been there two or three hours, so that it is to a great extent passed into the intestine unchanged and does not irritate the gastric mucous membrane as does salicylate of soda, which is decomposed almost as soon as it enters the stomach. The alcoholic solution of the new compound, aspirin, having such a bad taste, the drug was usually given in capsules. Its therapeutic effects are identical with those of salicylic acid, except that disagreeable gastric symptoms are almost entirely done away with.

Treatment of Appendicitis.—Osler ("Practice of Medicine") deprecates the attempt to treat appendicitis by any of the ordinary medicinal agents, holding that the disease is essentially surgical in character and that operation is indicated, whether a tumor exists or not, when by the third day the features of the case point to a progressive lesion. The mortality from early operation is very slight. The use of opiates or of salines or other cathartics is to be condemned, as the former may serve to mask the symptoms and the latter prevent the limiting adhesions by causing general peristalsis. The surgeon may be called in too late, but he can never be called too early.

Test Meal in Diseases of the Stomach.—The Ewald and Boas breakfast is the best test (Einhorn, "Diseases of the Stomach"). One or two rolls (35-70 gms.; 9-18 ʒ) and one cup of tea or water (300-400 c.c.; 10-13 ʒ)

are taken in the morning in a fasting condition. Thus any other particles of food, as meat or asparagus, if found in the gastric contents would evidently have remained from a previous meal. One hour after the meal the gastric contents are removed. They are best obtained by means of the soft rubber tube, which should have several openings at its lower end, and a glass tube from three to five inches in length at its upper end. This tube is first immersed in a pitcher of warm water. The patient, a bib or towel around his neck, sits holding a wide-mouthed bottle in his left hand, near his chest; the physician takes the tube from the pitcher, places the glass end-piece in the bottle, the patient opens his mouth, and the tube is inserted to the pharynx. The patient is told to swallow once or twice, and the tube is rapidly pushed with the right hand into the stomach (about 45 cm., 18 inches). (The physician need not introduce his finger into the patient's mouth.) The best method of ejecting the gastric contents is for the patient to exert pressure upon his stomach by means of his abdominal muscles (the Ewald-Boas expression method). The patient inspires deeply and then compresses his abdominal muscles in the same manner as during defecation. The gastric contents are thus expelled through the tube into the bottle. Before removing the tube the glass opening must be occluded. Then the tube is withdrawn quickly. The ingesta thus obtained are filtered and the filtrate is tested for: (1) Reaction. (2) Hydrochloric acid. (3) Lactic acid. (4) Acidity. (5) Propeptone. (6) Peptone. (7) Pepsin. (8) Rennet ferment. (9) Dextrin. (10) Erythrodextrin. (11) Achroodextrin. (12) Maltose. All these tests are described at length.

[Stomach-tubes are now made for this purpose, which are provided with a large bulb midway along their course. This bulb is compressed, after which it receives the stomach contents.]

Treatment of Chorea.—ANDERSON ("Contributions to Clinical Medicine") says that antipyrin, with the exception of some of the other coal-tar derivatives, is the only drug from the use of which cure may be confidently expected in the treatment of chorea. It is not the dangerous drug which it is commonly believed to be, but may be given with safety in very large doses even to children if the initial dose be small, and increased very cautiously. In many cases in which bad results have followed the administration of antipyrin the fault has been either in some impurity in the drug, or in an idiosyncrasy on the part of the patient. The initial dose should never be larger than 10 grains, and, if no bad results follow it should be rapidly but cautiously pushed until doses of 20, 30, or even 40 grains thrice daily are given. If nausea or vomiting occur, the drug should be omitted for a day or two. The results of this treatment of chorea are particularly good.

Treatment of Migraine.—W. H. THOMSON ("System of Practical Medicine," vol. iv). At the beginning of the attack, whether the stomach is full or not, lavage is of great value in the treatment, as it is important that all irritating substances should be removed from the stomach, and spontaneous vomiting does not always produce that result. Ergot is chief among the drugs to be used in treating the headache. It should be given in full doses, 1 dram of the fluid extract, combined with the same amount of the elixir of cinchona, repeated in two hours if necessary. If the drug causes the stomach to rebel, as is sometimes the case, the same dose, diluted with 2 ounces of warm water, may be given by the rectum. The coal-tar derivatives are very often efficacious, if the patient remains quiet after the administration of the drug, and the effect is increased if a dram of the aromatic spirits of ammonia in water be given just after the 10 or 15-grain dose of antipyrin or phenacetin, which should be repeated in three hours if necessary. In some cases the nitrate of strychnin, in doses of $\frac{1}{40}$ of a grain, or the tincture of nux vomica, in doses of 10 drops is useful when the antipyrin or phenacetin seems to be losing its effectiveness. In other cases relief is best obtained by the use of caffein in doses of from 2 to 3 grains, repeated in one hour if necessary. These are the cases in which nausea and vomiting are not prominent symptoms. Five- to 7-drop doses of the tincture of gelsemium, combined with from 15 to 20 grains of ammonium bromid, will often relieve the headache, but not the nausea. But the most important therapeutic indication is to prevent the recurrence of attacks. Systematic open-air exercise of a pleasurable kind, but not involving muscular fatigue, and elimination from the diet of such articles of food as are found by experience to cause attacks, are indicated. Except in the cases in which gastric catarrh (a condition which is not often found in migrainous patients) is present lavage of the stomach is contraindicated. The stimulating effect of a tumbler of hot water containing 1 dram of sodium phosphate and 1 grain of quinin or 5 grains of sodium salicylate on rising in the morning will often prevent the occurrence of headache. The acidulated preparations of phosphorus and pepsin are often beneficial, as:

℞ Acidi phosphorici diluti . . . ℥ iss
Tinct. nucis vomicæ . . . . ℥ ii
Syr. hypophosphitis . . . q.s. ad ℥ vi.
M. Sig. Two teaspoonfuls in water after meals; or

℞ Acidi lactici . . . . . ℥ iv
Ess. pepsinæ . . . . . ad ℥ vi.
M. Sig. Two teaspoonfuls after meals.

In cases in which the attacks occur with tolerable regularity at about a week's interval, the habit may be often broken up by the administration of 1½ grains of calomel in six fractional doses, given at quarter-hour intervals, followed by a saline cathartic on the day before the attack is expected. When patients have intestinal dyspepsia with brown tongue, mercurial laxatives are indicated and it is well to follow these with a systematic course of 10 grains each of salicylate of bismuth and sodium benzoate in capsules, to be taken one hour after meals.

For Hypertrophied Tonsils.—CASPEX advises irrigation twice a day, using the following solution:

℞ Resorcin . . . . . gr. lxxx
Betanaphthol . . . . . gr. v
Aquæ . . . . . Oii.
M. Sig. For irrigation of tonsils and pharynx.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

J. RIDDLE GOFFE, Ph.M., M.D., Editor,
No. 111 Fifth Avenue, New York.

Subscription Price, including postage in U. S. and Canada.

SATURDAY, AUGUST 12, 1899.

SANARELLI AND THE PATHOGENIC ROLE OF THE BACILLUS ICTEROIDES.

Much has been written in this country in criticism of Sanarelli's work on yellow fever. It has been a fair and shining mark for the shafts of the general commentator as well as the bacteriologist. With its author at a good and seemingly safe distance away it has been comparatively easy to find more or less obvious objections to his technic and rather patent faults in his conclusions. We are very glad, then, if for no other reason than for the sake of the good old-fashioned American spirit of fair play, to be able to present this week to our readers Professor Sanarelli's answer to his critics. We venture to say that it will be found effective and complete. While it is a little more personally controversial in tone than we might have wished, we think that there will be found in the circumstances that called it forth some justification for thus treating the subject.

Sanarelli proves well able to dispose effectually of certain objections that carried considerable weight against his theory of the specificity of the bacillus icteroides in yellow fever. The fact that the bacillus described by him was able to withstand exposure to very low temperatures without losing its vitality or virulence has been supposed especially to militate against the notion of its etiological connection with yellow fever, since that disease, as is well known, usually disappears at once after the occurrence of the first frost. This behavior of Sanarelli's bacillus in the presence of low temperatures, first brought to public attention by Novy in the columns of the Medical News, has been a favorite argument against the value of Sanarelli's work by those who controverted his conclusions as to yellow fever. Sanarelli, we think, shows that the objection really has no weight, and that though many micro-organisms cease to reproduce their kind so luxuriantly at low temperatures as they do at higher ones, yet they by no means lose their vitality, but may be awakened to reproductive activity by favorable conditions. His reference to some of our American yellow-fever epidemics during which the disease raged virulently despite zero weather is an especially telling point in favor of this view.

In general it way be said that while at first the current of bacteriological criticism set in strongly against the acceptance of Sanarelli's discovery the present trend of bacteriological literature is quite as strongly in his favor. Sanarelli himself has been able to make abstracts from no fewer than twenty-two papers which have appeared during the past year whose authors are all agreed that the bacillus icteroides is the cause of yellow fever. The writers are all practical bacteriologists who, in various countries (at least four), have done experimental work with the bacillus, and whose conclusions are the result of their study of some special feature of the pathogenic properties of the new microbe.

One of the most striking testimonies recently presented is contained in a private letter to Sanarelli himself from the head of the United States Yellow-Fever Commission of the Marine Hospital Service, which has been conducting its investigations at Havana. The letter is dated May 31, 1899, and expresses the heartiest commendation and sincerest admiration for Sanarelli's great work and the Commission's entire agreement with his conclusions.

The letter is all the more interesting as it anticipates the official publication of the final results of

the investigation which will only come in the regular course of official reports. It would seem, then, that as far as practical applications are concerned the medical world is bound to accept the weight of authority that has accumulated in favor of Sanarelli's discovery as a sufficient guarantee of its genuineness and that quarantine and therapeutic work in yellow fever at all our exposed ports must be carried on with this idea in view. The definite acceptance of the bacillus icteroides as the cause of yellow fever will simplify studies of the disease, make precautions against it easier to take, and, above all, will arouse medical and general confidence in the promising method of treating the disease by an antitoxic serum that Sanarelli's own work has pointed out as feasible.

ANTISEPTICS IN FOODS.

The adulteration of food is so often a harmless cheat that little notice is taken of it. One form of adulteration, however, which is only a few years old, has received considerable attention from scientists and physicians and under the title "embalmed beef" recently interested every one in America, from the President to the smallest newsboy. We refer to the addition of antiseptics, especially salicylic and boric acid, and more recently formalin, to perishable foodstuffs. How bitter were the denunciations of men who would add these things to the soldiers' meat! How calmly we go on allowing the sale of milk which contains them to feed the poorer children of our cities!

This may seem like an unwarrantable assertion, but there is strong probability that it is the exact state of affairs, judging from the meager reports of analyses published in America, and the fuller ones published by Public Analysts in England. In the latter country there have been officials of this character since 1860, and a great deal of law-making to prevent the adulteration of foods, and numerous convictions with some pretty severe penalties for infringements. And yet, in the report of the Public Analyst for Birmingham for the three years ending March, 1899, it is stated that one of the three antiseptics mentioned above was found in 460 out of 2300 specimens of food examined, just 20 per cent. Boric acid was found in 35 per cent. of the 882 specimens of butter examined, sometimes in such quantity that the water in the butter would not contain it, and it existed partly in crystals. More recently it has been in part superseded by formalin as a preservative for milk, this substance being found in 47 out of 1000 specimens examined.

Here is a field which invites the more assiduous attention of the Board of Health of our own city. While not inclined to deprecate the value of the scientific investigation of rabies, for example, it is of more immediate concern to know that foods are free from such injurious preservatives, and especially that milk is not so polluted. Not only do these chemicals render it difficult of digestion, but they enable a dealer to pass off stale milk, or milk which has been carelessly handled, as fresh, clean milk, thus doing the consumer a double injury.

OPERATIVE INTERVENTION FOR TUBERCULOSIS OF THE KIDNEY.

In his paper on "Tuberculosis of the Kidney as an Indication for Nephrectomy," which we publish this week, Dr. Reynolds deals in a very practically suggestive spirit with a difficult question in surgery. The battle with that most fatal scourge of humanity, the white plague of the North, tuberculosis, is on all along the line and surgical intervention for its lesions is, when practicable, the ideal treatment. The present work in renal surgery for tuberculous conditions is thoroughly scientific and conservative and is worthy of the best effort on the part of those who have to do with the surgery of this organ. The methods and results of the work deserve careful attention and study.

The catheterization of the ureters in the female, thanks to the work of Kelly and Pawlik, has become comparatively simple and when combined, as suggested in Dr. Reynold's paper, with centrifugation of the urine and injection of the sediment into susceptible animals, the procedure constitutes a diagnostic auxiliary that is almost infallible and which can be relied on to furnish unfailing indications for or against even so grave a surgical procedure as nephrectomy.

We no longer believe that micro-organisms can pass through a healthy kidney, and therefore when we are able to demonstrate in the urine taken directly from a ureter the presence of tubercle bacilli, it points inerrably to the existence of a tuberculous

focus somewhere in the upper urinary tract of that side. The indication thus furnished for nephrectomy is an absolute one.

It must be remembered, moreover, that the recent labors of Caspar and Nitze in Berlin and of their followers all over the medical world, have made it evident that catheterization of the ureters in the male is very often, certainly in a majority of cases, not only possible but comparatively easy. The collection of the urine directly from a ureter gives much more reliable information than does even an exploratory lumbar incision since the external surface of the kidney when exposed to inspection may be perfectly healthy, and yet a tuberculous focus exists in the interior of the organ. Communications of pathologic processes occur much more readily with the pelvis of the kidney than they do with its external surface. When the tuberculous foci are very limited in extent and therefore most hopeful for operation, they will often permit the discharge of tubercle bacilli into the urinary passages. The chances for early diagnosis and operation are rendered with this method very promising indeed.

It would seem, then, to be only a question of a short time until the puzzling cases of progressive tuberculous renal trouble running their course without any definitely pathognomonic symptoms that reveal the real cause with any assurance to ordinary diagnostic methods will cease to be the *opprobrium medicinæ* they have been up to the present time. The most striking uniform symptom in such cases is often a hopelessly progressive emaciation, which yields to no medicinal treatment and so makes them veritable nightmares for the medical attendant having them in charge. The encouraging results reported by Dr. Reynolds appear to indicate that these sad cases are now brought within the realm of hopeful therapeutics, and justify an abundant confidence in the future of renal surgery for tuberculous conditions.

ECHOES AND NEWS.

Yellow-Fever Epidemic Disappearing.—It was reported on August 7th that no new cases of yellow fever had developed at the Soldiers' Home at Hampton since August 1st. The patients at the Home are all convalescing.

New Trees in the Adirondacks.—Professor John Gifford, who has been elected to the chair of forestry in Cornell, reports that over a million small trees of different varieties have been planted within the past year on the 30,000 acres owned by Cornell near Axton in the Adirondacks.

Sir William Stokes and the International Medical Congress.—Sir William Stokes, Surgeon-in-ordinary to the Queen of England has been appointed and has expressed his willingness to serve as one of the honorary presidents of the International Medical Congress, to be held in Paris next year.

Cows Spread Typhoid Fever.—Thirty cases of typhoid fever occurred in Flushing, L. I., during July. It is declared that the disease was spread by one milkman, whose name is withheld, who has a pond of stagnant water on his place in which are typhoid-fever bacteria. His cows had been drinking this water.

Lunacy in England and Wales.—In England and Wales the lunatics on January 1st of the present year numbered 105,086, an increase of 3114 over 1898, the largest increase yet recorded. An analysis shows this spread of lunacy is not confined to any one class, although naturally the largest increase is among paupers. The situation is regarded as so alarming that an early official inquiry is demanded into the causes and the best means of combating them.

Race Winnings and Charity. — It is reported that the Duke of Westminster has presented the sum of £10,000, the amount won by his horse, Flying Fox, in the Eclipse stakes at Sandown Park some weeks ago to the Royal Alexandra Hospital, Rhyl, of which His Grace is president. The London *Lancet* says in comment on the matter: "We commend this excellent example to other owners who race for the love of the sport and not for filthy lucre."

Trained Chiropodists for the British Army.—As so much depends on the soldiers' feet in the movement of large bodies of troops, the British Army authorities have decided to train certain of the non-commissioned army officers in chiropody. The experiment has been tried already and has been found to add greatly to the efficiency of the troops. It is thought now that a permanent corps of chiropodists will be trained as soon as possible, and their services made available for all the infantry battalions.

A Surgeon behind His Gun.—The London medical journals make much of the fact that at the recent army contests in sharp-shooting in England the most consistent shooting at the meeting was done by a member of the medical profession. Surgeon-Lieutenant Bertram of the Canadian team proved to be the best general score-maker and comes home as a consequence with a number of medals and prizes, though not with the medal for the best marksmanship, for which he was beaten by a slight margin.

Comparative Mortalities from Tuberculosis. — According to recent statistics published in *La Nature* the following is the number of deaths per million of inhabitants annually from tuberculosis in the countries named. In France, 2823 per million; in Switzerland, 2715; in Hol-

land, 1918; in Japan, 1194; in Austria, 3682; in Italy, 1340; in England, 1568. In all of them there has been a notable reduction of the mortality in recent years, and it is hoped to still further reduce the mortality from the dread disease.

An Epidemic of Poliomyelitis.—An epidemic of what Dr. J. W. Poucher, a resident of Poughkeepsie, N. Y., considers to be poliomyelitis has been prevailing among the children of that city. Up to August 4th there were fifty cases, with but one fatality, which possibly was really a case of spinal meningitis. The causation up to that date had not been satisfactorily demonstrated. Drs. D. M. Sheedy of Poughkeepsie and H. D. Chapin of the Post-Graduate Hospital, New York, are making microscopic and other investigations.

A New Theory in the Etiology of Appendicitis.—Dr. Alexander Haig, whose works on gout and uric acid are well known, recently suggested that in a large number of cases of typhlitis and appendicitis the primary lesion was a gouty affection of the fibrous tissues in the neighborhood of these structures. He suggested also that the proper treatment for many cases under these circumstances was the administration of large doses of salicylate of soda or other salicylates. Of course a certain number of cures with the remedy have already been reported, others will doubtless follow.

Aural Menstruation.—The Paris correspondent of the *Medical Press and Circular*, London, reports a case of this anomaly related by Dr. Lermoyez of Paris. The patient had each month prodromic symptoms such as lassitude and headache, and then a thin stream of blood flowed from the right ear. No lesion of any part of the organ could be discovered. The tympanum was intact, but the cutaneous vessels of the external auditory canal were much enlarged. At the end of three years the vicarious menstruation ceased and the menses came through the ordinary channels.

Smallpox Outbreaks.—Up to August 3d there had been some thirty cases of smallpox in Pittsburg, and neighboring towns, all of which places are on the line of the Pennsylvania Railroad. No money has been appropriated for the establishment of a quarantine, and an appeal has been made to the Westinghouse Electric Company for funds for the purchase of vaccine virus and for quarantine expenses. An epidemic of smallpox has broken out in Claiborne County, Tenn., on the Kentucky border. It is believed that the efforts of the authorities to prevent the spread of the disease will be successful.

Caterpillar Rash —There is a tradition in some parts of the country that the handling of certain species of caterpillars produces a rash. A correspondent of the *British Medical Journal* for July 29, 1899, reports a series of such cases in children who had been handling caterpillars of the woolly-bear variety, the ordinary, brown, hairy caterpillar. The lesions were erythematous patches accompanied by almost intolerable itching. The spots appeared on exposed parts of the face and neck though the hands were not affected. The itching yielded to ordinary remedies and the erythema disappeared in twenty-four hours.

Munchausen up to Date —The following testimony was recently given by a woman at the anniversary services of faith-cure believers, which was held at Mount Zion Sanctuary in Chapel avenue, Greenville, New Jersey: "This man when young, spilled some acid in his eyes and destroyed the sight of both. The physician removed his eyeballs and he was totaliy blind for many years. He was finally persuaded to pray for the restoration of his sight. Shortly afterward he felt something growing in the places where his eyeballs had been. New eyes were given to him, and to-day he can see as clearly as any person here."

Tuberculosis in Cattle.—The special Assembly committee appointed to investigate the operation of the present laws in relation to tuberculosis and other contagious diseases in animals and infections in animal products met at Albany on August 1st. Dr. Edward Moore, a veterinary surgeon of Albany, declared that when tuberculosis in cattle is common human tuberculosis is so rare as to bear no relation to it and that bovine tuberculosis is not communicable to man. Dr. Moore declared that the State Board of Health has failed to produce facts to prove its contention that bovine tuberculosis is communicable to the human subject.

The Doctor and His Patient —Professor Osler, in an address delivered before the students of the Albany Medical College recently said: "You must feel that you have entered upon a profession that appeals both to the head and to the heart. Dealing as we do with poor, suffering humanity, we see the man unmasked, exposed with all his frailties and weaknesses, and you have got to keep your heart pretty soft and pretty tender not to get too great a contempt for your fellow creatures. The best way to do that is to keep a looking-glass in your own hearts, and the more carefully you scan your own frailties the more tender you are for the frailties of your fellow creatures."

Cockles and Typhoid Fever.—According to the London *Lancet* a number of cases of typhoid fever have been occurring recently in and around Chichester, England, whose origin has been wrapped in mystery. Since the beginning of the year fifty-five cases have occurred. In not less than twenty of these it was found on careful inquiry that cockles had been eaten within ten days of onset of the fever. It has practically been decided by the authorities that the cockles, which are gathered from places somewhat liable to be affected by sewage, may be the cause of the disease, and that not alone the more delicious bivalves, but the more vulgar shell-fish may contain the germs of disease. Bacteriological investigations to absolutely decide the question are now in progress.

The Appetite of the Russian.—The *Philadelphia Telegraph* describes the dinner given by a Russian naval officer, at present staying in Philadelphia, to his brother officers. By way of an appetizer there was served salt fish,

smoked salmon, imported herring, bologna sausage, pickles, potato salad, vodki—Russian whisky—and American whisky. An hour later the dinner proper began. A Russian vegetable soup "of excellent savor, but unspellable, and to an American unpronounceable" was first served. Next came a whole baked salmon "of regal dimensions" stuffed with brown, cracked wheat. This was followed by an entire roast pig, whose "in'ards" were filled with vegetables. Next came a peculiar Russian pie of meat, fish and vegetables, cut into slices and garnished with mustard. Then a Russian salad and lastly dessert, the whole having been convoyed with champagne and liquors galore.

Next Year's Congresses at Paris.—More than 100 international congresses of various kinds are to be held in Paris next year during the course of the Exposition. A certain number of these of more special medical interest have already been announced in the columns of the MEDICAL NEWS Just about the time of the International Medical Congress that of from August 2th to 9th the following congresses on subjects of more or less importance to medical men are to be held: An International Congress of Applied Chemistry from July 23d to the 31st; International Congress for the Amelioration of the Condition of the Blind, August 5th; International Congress of Public Charities and Philanthropy, July 30th to August 5th; International Congress of Deaf Mutes during the first week in August; International Congress of the Medical Press sometime during Medical Congress week; International Dental Congress, August 8th–14th; International Congress of Professional Relations and Deontology (the science of duties) from July 23d–28th; International Congress of Psychology, August 22th–25th; International Congress of Hygiene, August 10th to 17th.

Anchylostomiasis in Belgium.—According to a recent report of the French resident consul at Liege, in Belgium, anchylostomiasis, that is, the anemic condition due to the growth of the so-called anchylostomum duodenale in the intestines, is very prevalent among the coal-miners in the neighborhood of Liege. It has attacked principally the older miners. The disease is caused by the swallowing of anchylostomum eggs which usually find their way into the drinking-water of the workman because of carelessness about cleanliness and negligence in the matter of excreta. There has not been so far as we know any epidemic of the disease in this country but any one afflicted with the disease might easily bring about its introduction and the habits of our workmen in mines, tunnels, brickyards and the like, where infection usually takes place are such that the disease would readily spread. Meantime obstinate cases of anemia occurring particularly in men who come from the Low Countries, or from the region around Dusseldorf or Cologne on the Rhine, or from the Northern part of Italy, should be suspected and their tools carefully examined for the eggs of the parasite.

International Congress of Hypnotism.—The Second International Congress of Experimental and Therapeutic Hypnotism is to be held next year in Paris from August 12th to 15th. The last international congress on this subject met in 1889. The next meeting is to be held under the auspices of the French Society of Hypnology and Psychology, which has over 150 members and publishes a monthly magazine the *Revue de l'Hypnotisme.* The acting president of the forthcoming congress is Dr. Jules Voisin, the well-known alienist and author of several works on idiocy and allied subjects, who is one of the attending physicians at La Salpétrière. A number of well-known authorities on the subject of hypnotism have expressed their willingness to be present and read papers, among others Professor Grasset of Montpelier, Drs. Vogt of Berlin, Lloyd Tuckey and Milne Bramwell of London, Schrenk-Notzing of Munich, Bernheim and Liegois of Nancy, Tokarski of Moscow. A number of invitations have been issued and those who are interested in the subject and contemplate attending the meetings, are asked to communicate with Dr. Nerillon, 17 Rue des Beaux Arts, Paris.

Medical Education in Kentucky. — The State Board of Health of Kentucky has given notice that it will hereafter refuse to recognize as a basis for certificates to practise medicine diplomas from any medical college which does not in good faith comply with the requirements of the American Medical College Association, the American Institute of Homeopathy, and the American Eclectic Medical College Association, respectively, both as to preliminary education and four-years' course of study. This means that no school that graduates three-year students will be recognized in Kentucky hereafter. The Board provided an examination for three-year graduates of the present year, as many of the students had attended such schools in ignorance of its advanced requirements, but found this course unsatisfactory, a large percentage of the examinations indicating incomplete preliminary education as well as imperfect medical training. This standard for the State of Kentucky was made and promulgated in 1891, to take effect the present year, but is again published that schools patronized by Kentucky students and future graduates expecting to practise in the State may fully understand the requirements of the Board.

MEDICAL MATTERS IN NEW YORK.

COMPTROLLER'S PLAN TO RETRENCH—BOGUS HEALTH INSPECTORS—DR. CROWE IS "WANTED"—PATIENTS SAY THEY WERE CLUBBED— DEATH-RATE IS LOWER —REPORT OF CONTAGIOUS DISEASES.

COMPTROLLER COLER is preparing plans for cutting down the city budget for 1900. If these are carried out the city will be saved at least $5,000,000 next year. In the very first place Mr. Coler will recommend a big reduction in the amount of money appropriated to charitable institutions controlled by private corporations or individuals. He will urge that many such institutions be cut off the list and that the amount allowed to others be reduced. His plan, if adopted, will result in a saving of possibly $1,000,000 a year in the appropriation for public charity alone.

A number of unauthorized persons have been visiting

private houses in the guise of sanitary inspectors in the service of the Health Board. Some have demanded fees and others have attempted a species of blackmail, threatening to perform obnoxious acts if they were not "called off" by means of money bribes. A woman complained on August 3d to President Murphy of the Health Board that a man exhibiting a card on which was printed "H. Burnet, M.D.," called and insisted, in the name of the Health Board, on going through her house. He wanted to take some of the furniture away to be disinfected, and he also wanted to look over all the clothing in the house.

Dr. S. W. Crowe of No. 228 West Forty-seventh street is wanted by the police, firstly, for disturbing the peace, and secondly, to pay damages, *to wit:* "to one hole burned in the asphalt of Longacre Square." The facts in the case are about as follows: One William Waldorf Astor, erstwhile an American citizen, has become a humble subject of a foreign potentate. This renunciation of allegiance to these United States greatly incensed Dr. Crowe, whose patriotism seems to be of an exceedingly virile and robust sort. Dr. Crowe expressed his contempt by making an effigy of Mr. Astor, which, with a barrel filled with combustibles and several gallons of kerosene, was put on a truck, the doctor having been aided in the transfer by some thirty of his fellow patriots, each of whom he rewarded by the payment of $2. The truck was then driven down Broadway to Thirty-fifth street, followed by an admiring crowd, until it reached the saloon owned by Mr. John L. Sullivan, at one time a noted pugilist. Here Dr. Crowe "set up the drinks" for everybody in sight, after which his enterprise had the honor to receive Mr. Sullivan's unqualified commendation. "This country would be all right," said this exemplary "gent," "if all the citizens wus like you." The procession augmented on the route by hundreds of Tenderloin habitués, then returned to Longacre Square, many exciting incidents transpiring on the way. Here the "cop" being, as usual, conveniently absent, the effigy of Mr. Astor was burned, the assembled multitude applauding vociferously the while. During the burning Dr. Crowe made a speech, which was disturbed by the altogether unexpected arrival of the "cop," on seeing whom Dr. Crowe cut short his speech and disappeared ignominiously in the crowd. Up to the present writing the police have not found him.

John Curtis was taken to Roosevelt Hospital on August 2d, suffering from a fractured skull. On the same day William Harvey, eighteen years old, was taken to St. Vincent's Hospital, suffering from a broken jaw and other injuries. In both these cases it is declared the clubs of policemen did the damage; and there is not the slightest reason to doubt the assertion. These incidents are details which, with many others, show how we are reverting to the halcyon days of Tweed, and, how, even in those days, the city was not so outrageously misgoverned as it is to-day. In this connection we recall the classic excuse of the "cop" who was accused of unnecessary clubbing. "Sure, it wasn't me hit him. He run up agin me noight-stick."

The report of the Bureau of Vital Statistics for the week ending July 29th shows 821 deaths in the borough of Manhattan, against 848 for the corresponding week last year. The percentage was 20 24, as against 21.60. There were twenty-five deaths due to "heart-failure". This phrase is often used to avoid specifying the cause of death. It means no more than "failure of respiration" would. Such cases should be referred to the coroner.

Following is the report of contagious diseases for the week ending August 5th: Measles, 156 cases, 8 deaths; diphtheria, 155 cases, 19 deaths; croup, 1 case, 4 deaths; scarlet fever, 54 cases, 5 deaths; chicken-pox, 8 cases; tuberculosis, 150 cases, 122 deaths; typhoid fever, 43 cases, 15 deaths; cerebrospinal meningitis, 11 deaths; totals, 567 cases, 184 deaths.

MEDICAL MATTERS IN CHICAGO.

A CASE OF DIVINE HEALING—A NEW HOSPITAL TO BE ADDED TO THE MATERNITY DISPENSARY OF THE BUREAU OF ASSOCIATED CHARITIES—YOUNG WOMAN'S AUXILIARY CHARITY—MEDICAL BOARD OF THE DISPENSARY — VIOLATION OF ICE REGULATIONS—COLLECTION OF GARBAGE TO BE UNDER THE CONTROL OF THE CITY HEALTH DEPARTMENT.

As a result of the disclosures made concerning the death of Mrs. Annetia Flanders, who was treated with "divine healing" by a Mrs. Bratz, the State Board of Health has decided to institute an investigation of the "divine healing" method, as carried on by the Zion Home and the Divine Healing Mission of Dr. John Alexander Dowie, under whose direction Mrs. Bratz practises. Attorney John A. Barnes, counsel for the Board, will enter suit against Mrs. Bratz for practising in the Flander's case without a license. He will also take immediate steps to secure the revocation of the license of Dr. John G. Spelsher, who is an official of the Dowie Institute, on the charge that the latter has made a practice of signing death-certificates without finding out the cause of death. It is the intention of Attorney Barnes to summon all the officials of the Dowie Institute as witnesses to testify on the process of "divine healing." The evidence which he has obtained concerning the death of Mrs. Flanders has warranted an order from the State Board of Health for an examination into the practices of the promoters of this institution. The State Board of Health has been after them for a long while, and Mr. Barnes believes that he has procured tangible means of bringing certain persistent offenders to justice. There is not much question in his mind that the developments will surprise persons who are not familiar with the work of Dowie.

Adherents of the faith of divine healing insist that they are exempted from prosecution by the same law under which the State authorities expect to proceed. This act provides that "any person who treats or prescribes to treat any physical ailment or injury without a license shall be liable, and that the act shall not apply to surgeons of the United States Army, Navy, or Marine Service in the discharge of their official duties, or to any person who ministers to the sick and suffering by mental or spiritual means without the use of any drug or material remedy."

The outcome of this case will be watched with much interest both by the laity and the medical profession.

During this month a hospital will be added to the maternity dispensary of the Bureau of Associated Charities. It will be in Ashland Boulevard. During the five years the institution has been established members of the medical staff, including Drs. E. J. Doering, Henry T. Byford, N. S. Davis, Jr., and Henry B. Favill, have attended 3000 maternity cases in individual homes. While the outside work will be continued, it has been found advisable to provide a hospital where patients may be taken from their unsanitary surroundings and properly nursed during illness.

A charity which has been conducted in connection with the dispensary, and which will continue with the hospital, is that of the young woman's auxiliary, which supplies clothes for the mothers and their infants. The hospital will be under the direct supervision of Mrs. E. C. Dudley, wife of Dr. E. C. Dudley, with Mrs. E. E. Koch as head nurse.

The dispensary was founded by Dr. Joseph B. DeLee, who appreciated the necessity of providing scientific treatment for the poor in maternity cases. He also realized the great value such work would be to students of medicine, and since the inception of the scheme he has labored untiringly for its success. The work has progressed and is increasing steadily.

The medical board of the dispensary consists of four consulting physicians, three obstetricians, ten physicians for the treatment of special diseases, and eight resident physicians. During the year ending February, 1899, 93 students and 17 doctors, including internes, were engaged in the work, and 10,631 visits were made to patients. Students were furnished by eleven colleges, among them being Rush, College of Physicians and Surgeons, the Northwestern University Medical School, University of Michigan, the Toronto Medical College, etc.

Imperative orders to arrest all violators of the ice-inspection regulations were issued by Commissioner of Health Reynolds a few days ago. The intention is to catch the small retail dealers, expressmen, and peddlers, who engage in the trade without paying a license, thereby escaping the inspection system. Dr. Reynolds estimates that there are more than one hundred of these small offenders. They sell ice in the poorer districts in direct violation of the inspection regulations and contrary to the general health ordinances. The department officials say they procure ice which, under the department regulations, should be used for cooling purposes only, and retail it for culinary and domestic purposes. This is considered a menace to the health of the purchasers, and for this reason Commissioner Reynolds is having his subordinates make a hard effort to break up the practice.

Control of the collection of garbage by private contractors will soon be entirely in the hands of the Health Department of this city, and Commissioner of Health Reynolds promises to enforce regulations which will remedy the existing conditions. At its last session the city council passed an ordinance authorizing the Health Commissioner to license private garbage collectors and to establish regulations governing the traffic. So soon as Dr. Reynolds completes his regulations, upon which he has been working for some time, they will be put in effect. The private collectors who do the work in the down-town districts have no connection with the city garbage forces. They simply remove refuse from hotels, restaurants, and wholesale establishments, from which collection by the city is not required in the ordinances.

CORRESPONDENCE.

AS OUR FRIENDS SEE US.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—Some years ago the *New York Medical Journal* did me the honor to publish an article treating of the correct formation of new medical terms. Since then much has been said about "purity" of the linguistic source of such terms. The papers in your issue of April 22, 1899, set me to thinking on the subject again. In all these discussions I have not observed that any one considers the common origin of Greek, Latin, Russian, Teutonic, et cetera, and, of course, a nearness of spirit in the natural forming of thought-expressing vocables. In the physiology of animal and vegetable forms the wise selection and combination of individuals from kindred stocks usually produce good results. In the making of new, significant expressions, why not choose those which will give (1) the meaning; (2) ease of enunciation; (3) terseness; (4) beauty of sight and sound. When we consider the source of the various elements thus composed (or compounded) a liberal mind may well hesitate before deciding that they are hybrid. Hybrids die out; such forms live on.

Permit me to express my pleasure and appreciation anent the excellent conduction of the MEDICAL NEWS. During recent months I have especially enjoyed the editorials for the judicial and judicious tone, together with the evidences of the mind, esthetical in rhetoric and poesy, that lives and shines through all.

Sincerely yours,

FRANKLIN B. STEPHENSON,
Surgeon, U. S. N.

U. S. S. "OREGON,"
MANILA, PHILIPPINE ISLANDS,

ORIGIN OF THE PLAGUE IN EGYPT—SMALLPOX AND VACCINATION IN INDO-CHINA—COMPARISON OF TUBERCULIN AND TONALBUMIN OF TUBERCULOSIS—COLI BACILLI FOUND IN SPUTUM OF PURULENT BRONCHITIS—TREATMENT OF PELVIC HEMATOCELE—OPERATION FOR IMPERFORATE ANUS PERFORMED THREE DAYS AFTER BIRTH—RELIEF OF PROSTATIC HYPERTROPHY—BRONZING OF THE SKIN PRODUCED BY ARSENIC MISTAKEN FOR ADDISON'S DISEASE—VICARIOUS MENSTRUATION FROM THE EAR—TYPHOID FEVER IN PARIS.

AT the Academy of Medicine, July 4th, PROUST spoke of the reappearance of the plague in Egypt, after a free

interval of fifty-five years. The pilgrimage to Mecca could not in this instance be held responsible, since the outbreak occurred before the pilgrimage began. It came from Bombay, probably by a steamer. All of the forty-two cases officially reported up to date were of the bubonic type, except one pneumonic one. Forty per cent. of the cases were among Europeans. On account of the finding of dead rats in the houses, the physicians of Alexandria hold to the theory that these animals were instrumental in the spread of the disease.

Hervieux communicated to the Academy, July 11th, a note upon the ravages of smallpox in Indo-China, where there are no adequate measures against the spread of the disease, and where vaccination is pretty generally unknown, especially in the provinces. Smallpox causes more than two-thirds of the total infant mortality, and only five out of one hundred adults are without the marks of smallpox. To it is ascribed more than ninety per cent. of the cases of blindness. In Laos all the children were slain by an epidemic, so that the men were obliged to go to Siam for their wives, there being no young girls left in their own country. Hervieux urged the estalishment of compulsory vaccination, upon both humanitarian and economic grounds.

At the Biological Society, June 17th, Gouget and Bezancon compared the poisons produced by tubercle bacilli. Their experiments showed that besides the well-known tuberculins there is another poison produced by the bacilli—a toxalbumin. The former produce a rise of temperature when administered to guinea-pigs. The latter depresses the temperature. Like the toxins of tetanus and diphtheria it is destroyed by heat. The experimenters were not able to separate it perfectly from the tuberculin, so that their preparations sometimes caused hyperpyrexia, sometimes hypopyrexia, and sometimes the two reactions successively.

At the session of July 1st Notca said that he had found a certain number of cases of bronchitis in which the fetor seemed due to the presence of coli bacilli. In three of them he had succeeded in isolating this microbe from the purulent sputum.

At the Surgical Society, June 27th, Reynier reported two cases of dangerous hemorrhage following incision into a retro-uterine hematocele, once by the vaginal and once by the inguinal route. The patients were saved by the prompt performance of laparotomy, and he did not hesitate to say that such is the rational method of treatment of hematocele in Douglas' fossa—since severe hemorrhage is not an unusual concomitant.

Pozzi said that he had performed colpotomy, a great many times for retro-uterine hematocele, and if hemorrhage occurred, he had always been able to control it by tamponing with gauze.

Routier, July 5th, said that he was once an advocate of laparotomy for retro-uterine hematocele. He now reserved that operation for those cases in which the hemorrhage is plainly abdominal. When the hematocele is pelvic colpotomy is the natural operation. It is simple, gives free exit to the blood and placental débris, and the lesions in the tubes or ovary are usually so little advanced that they disappear by atrophy, without further operative treatment. The only objection to the operation seemed to be the danger of hemorrhage, and this ought to be controlled by tampons.

Chaput preferred colpotomy, reserving laparotomy for those cases in which there is severe and persistent hemorrhage.

Lucas Championniere said that laparotomy is not a more dangerous operation than colpotomy, and is preferable to the latter in the treatment of hematocele.

Tuffier classified cases of hematocele, that is, retro-uterine hemorrhage due to the rupture of a pregnant tube into adhesions in Douglas' pouch—as recent, old, or infected. In old and infected cases, colpotomy is the operation of choice, as it is less dangerous than a laparotomy, and equally as successful. It is otherwise in recent cases, for in these hemorrhage is to be feared. Twice he was obliged to leave clamps in position to control it. This is not surprising when one considers that the vascular supply is greatly increased not only at the site of the placenta, but in the omentum, intestine, and throughout the pelvic cavity.

Pozzi said that the matter could be summed up in the few words: perform a laparotomy if the tumor is abdominal and a colpotomy if it is pelvic.

Reyneir said that a few positive cases of hemorrhage had greater weight with him than many in which no hemorrhage occurred. He still insisted on the danger of colpotomy, which ought not to be undertaken unless all preparations had been made to go on with laparotomy if necessary.

July 12th, Broca described an operation performed upon a child three days old for imperforate rectum, the anus appearing normal. The operator, Caston, by a posterior perineal incision removed the coccyx, and found the lower end of the rectum nearly two inches (4 cm.) above the anus. It was drawn down with difficulty. The operation was successful. Comment was made that the operation performed was suitable to the case but was not to be recommended as a general operation for imperforate anus.

Pousson tested clinically the different indirect methods of overcoming hypertrophy of the prostate (orchidectomy, vasectomy, and angioneurectomy), all of which aim to overcome retention of urine by reducing prostatic congestion. Although this is an important factor, it is not the only one, and the problem of radical cure of hypertrophy of the prostate is far from solved. Regular catheterization, cystotomy, cystostomy, prostatotomy, and prostatectomy will each continue to find its application in certain cases. The attempt should be not so much to reestablish spontaneous micturition, as to provide for easy and complete evacuation of urine and thorough washing of the bladder by means of a catheter. The processes of the gland in the bladder produce angles which retain purulent urine after careful washing, and thus keep up the cystitis. Pousson performed prostatectomy eleven times with four successes as far as spontaneous micturition was concerned, and seven successes relative to the disappearance of cystitis and purulent urine.

At the Medical Society of the Hospitals, June 30th, ENRIQUET and LEREBOULLET showed a man aged forty-seven having a generalized melanoderma due to prolonged treatment with arsenic. For eighteen months he took daily 16 drops of Fowler's solution to cure eczema of the hands and feet. The bronzing of the skin appeared six months after he began to take the arsenic, and as he was thought to have Addison's disease the remedy was continued. No gastro-intestinal symptoms were noted, nor lumbar pains, nor general weakness. The amount of pigment and correspondingly the depth of yellow or brown, varied in different portions of the body. In general it was more marked in the folds of the flexor surfaces than elsewhere. There was almost no pigmentation of the hands and feet. Emaciation was only slight. After the drug was discontinued the color of the skin slowly changed toward normal.

July 7th, LERMOYEZ mentioned the case of a girl who began at the age of thirteen years to menstruate from the right external auditory canal, and who continued to do so every month for three years. Then menstruation from the uterus appeared and continued regularly, and the escape of blood from the ear grew less, and then appeared only every two or three months, and finally ceased altogether. There could be no doubt from the symptoms which preceded and accompanied this auricular hemorrhage that it was of catamenial character. The tympanum remained intact. The cutaneous vessels in the meatus were much enlarged, and the hemorrhage was produced by their rupture. There was no affection of the ear and the cause of the hemorrhage was difficult to determine. The girl could not be called hysterical, although there was present a certain degree of auditory anesthesia of the right side combined with a light hypo-esthesia of the tympanum and auditory canal. A coincidence of these two symptoms is one of the best-known signs of auricular hysteria.

THOINOT spoke of the prevalence of typhoid fever in Paris. When spring water was distributed through the city conduits to all the inhabitants it was hoped that the disease would disappear. Such had not been the case, however, and it was to be regretted that many of the sources of supply were not above suspicion.

WIDAL said that the populace was still ignorant of the need of boiling drinking-water and that it was the imperative duty of physicians to spread knowledge upon this point.

SOCIETY PROCEEDINGS.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF NEW YORK.

Stated Meeting, Held April 19, 1899.

THE President, WILLIAM STEVENS, M.D., in the Chair.

TUMOR OF THE STERNUM OF TUBERCULAR ORIGIN.

DR. J. BLAKE WHITE: The following interesting case came under my observation recently. The patient was an elderly woman, between sixty and sixty-five years of age, who came to me about a year ago complaining of a great deal of pain which was referred to the lower right edge of the sternum. This region was very sensitive to pressure. Shortly afterward a tumor presented at the junction of the ninth and tenth ribs with the sternum. As it was thought to be an abscess, an exploratory operation was advised. With Dr. Stevenson's aid the patient was anesthetized and an incision made over the tumor, which proved to be a tubercular growth springing from the edge of the sternum and apparently the result of a tubercular perichondritis. The tubercular material was cleaned out, the surface of the cartilages carefully scraped, and the cavity packed with gauze. The wound is now healing and the patient is doing well. The tumor doubtless originated from a tubercular focus aroused as a result of a traumatism received by the patient some time previous. No other evidences of tuberculosis are present, but two of the patient's five children died of pulmonary tuberculosis following typhoid fever and they manifested the most pronounced evidences of general tuberculosis that I have ever seen in an extensive experience. In one of these the disease was of the most malignant general type, nearly all the joints in the body being affected and showing marked tubercular degeneration prior to death.

ENLARGEMENT OF LYMPHATIC GLANDS DUE TO INFLUENZA.

DR. S. H. DESSAU: I have lately seen a number of cases of enlargement of the lymphatic glands of the neck and of the inferior maxillary region as a sequel of influenza. This condition is undoubtedly due to a septic process which is going on in the vault of the pharynx. Dr. Jacobi called attention to this fact some years ago, but not long ago it was supposed that the enlargement of these glands was usually tubercular and it was customary, especially among the German surgeons, to extirpate them at once. In some of the cases I have seen as a sequel of influenza they go on to suppuration but as a rule they subside under treatment of the catarrhal process. I recently saw in my clinic a case in which two glands were involved and the swelling was so great that the lobe of the ear was elevated. At one time they became fixed, which is usually an indication for surgical treatment. The child's mother was very anxious to have me remove the glands, but I persuaded her to wait. Under the internal use of calcium chlorid, alternated with iodid of iron, the swelling gradually subsided and the child made a perfect recovery. As an early treatment of the adenitis I have found a local application of a twenty-per-cent. preparation of oleate of mercury most satisfactory.

DR. S. N. LEO then read the paper of the evening, entitled

A CONSIDERATION OF OUR HOMES.

The paper, which was a most exhaustive one, dealt with the sanitary and hygienic arrangement of dwellings with reference to the propagation and spread of infectious and contagious diseases. According to the author faulty plumbing and damp cellars are often the cause of infectious disease, and carpets, draperies, picture-frames, and wall-paper, act as factors in spreading such disease, by

harboring dust and germs. He recommended that all plumbing, basins, closets, baths, and sinks, be situated in an annex and not in the dwelling itself; that cellars be made dry and kept clean; that all garbage be disposed of speedily, preferably by burning; that hardwood floors replace carpets, draperies be dispensed with, and wall-paper discarded for some hard finish which will permit of washing down the walls. He also suggested that a spare-room on the top floor of every house be set aside for use as a sick-room and for isolation. The importance of thorough ventilation was dwelt upon and methods of disinfection described.

DR. PALMER C. COLE: The scope of the paper is so vast that it is very difficult to discuss it. I agree with the author in regard to many points but not in all. For instance, I do not believe that moisture under a house will *per se* cause consumption. Nor do I think it is necessary to boil any material one or two hours for the purpose of disinfection. It has been shown that no spores will survive boiling for two minutes, therefore prolonged boiling is a waste of time. The same may be said of dry heat, for bacteria and spores of bacteria are immediately killed by being subjected for a few moments to a temperature of 210° F. In speaking of disinfectants, the author has omitted formaldehyd, which is one of the most powerful germicides we have. I first employed it four years ago in a case of scarlet fever, and since that time it has been recommended by the Board of Health. As to the dust in the air, we have this always with us. The air is loaded with bacteria, but, fortunately, most of them are harmless, and even the pathogenic bacteria must fall upon a fitting soil or they perish. Dust can never be eliminated from our modern dwellings. The model house which the author describes would indeed be desirable, but I fear it is an impossibility.

DR. CHARLES A. LEALE: the subject of the paper is a most interesting one and the author has covered the entire ground. I know a number of instances in which disease has been caused by defective plumbing and one in which prolonged ill-health was traced to the filthy condition of the water-tank. When tank-water is used it should previously be boiled. The bacterial source of disease in water may be destroyed by the addition of a small quantity of alum, which coagulates albumen and thus kills animal life. This was used here with benefit when cholera was prevalent years ago. I consider a paper of this kind of great importance, for I believe that we can do more for humanity by preventing disease than by medication. In regard to sanitation and disinfection, we will do wonders if we follow Nature's teaching. I was especially struck with this while making an ascent of Vesuvius and noting the results of sulphurous acid gas. The inmates of the monastery a little way down the mountain enjoy good health and live to a ripe old age because of the pure air which they breathe.

DR. ROBERT NEWMAN: Plumbing, ventilation, heating, and lighting are matters of such importance that they are made the subject of a course of lectures in nearly all our large colleges. The sanitary plumbing of late years is a vast improvement and is constantly being perfected. I am told that the plumbing of a house built five years ago is entirely out of date at the present time because of the improved methods now in use. Lighting by electricity is also a step in advance.

DR. S. H. DESSAU: The paper has brought to my mind the fact that physicians should educate themselves in sanitary science which, according to the author, embraces a knowledge of architecture as well as sanitary plumbing, ventilation and disinfection. A number of the suggestions offered impress me as very apropos, while others seem rather involved. The setting aside of a room on the top floor of a dwelling for use as a sick-room is a most excellent idea. I agree with Dr. Cole in regard to the value of formaldehyd. The danger of infection of draperies and wall paper will be avoided if the formaldehyd lamp is employed during the entire progress of the disease, for in this way the germs are destroyed as they are given off from the patient. I consider this disinfectant one of the greatest improvements of modern times. I regret that the author did not offer some suggestions in regard to the proper ventilation of a house, for this is a most important point. The over-heating of our houses and the lack of ventilation are sufficient to condemn them from a sanitary point of view. If the medical profession would take up some of the points brought out in the paper and would keep them before the public, the men who build houses would eventually be obliged to build them on a different plan.

DR. A. M. JACOBUS: The author has given us a beautiful picture of an ideal but impossible city house. We should, however, see to it that the cellar of the house in which we live is not damp and that the plumbing is in perfect order—and the latter, at least, can be made practically perfect if the laws are carried out (and modern plumbing installed). My experience has been that a great deal of sickness is due to foul air from a damp cellar being carried up-stairs through the heating apparatus and otherwise, but I do not believe that typhoid fever or diphtheria can be caused in that way. If infectious-disease germs be present in the house-drain or water-closet pipes and these be leaky, of course occupants of houses may thus become infected. Another thing which requires attention is the heating of our houses. The modern house, especially the apartment-house, is over-heated and badly ventilated; the result being that the inhabitants are always ailing and especially with neuralgic and other nervous as well as pulmonary troubles.

As to filters, I approve of and believe the porous stone kinds to be absolutely necessary to insure pure water and especially to remove malarial and typhoid-fever germs, but I believe those filters which are made of wire, gravel, or charcoal, etc., to be not only worse than useless, but absolutely to be hotbeds for the cultivation of germs.

DR. L. DUNCAN BULKLEY: There can be no doubt that defective plumbing is a fruitful cause of illness. In an instance of this kind, the patient, a man, was ailing for years, suffering from cold-sweats, fever, and exhaustion. The plumbing was thought to be at fault and it

was thoroughly inspected, the usual smoke and peppermint tests being made, but nothing was found. The patient was so convinced that the plumbing was the cause of his illness that he obtained permission from the owner to investigate for himself. This he did, beginning at the bottom and going up to the top of the house, laying bare all the soil-pipes, and he was rewarded by finding a lead pipe so corroded that he could put his finger into it. New plumbing was put in the house and the man has not been ill since. The case is interesting because the government tests which were employed did not reveal the leaky pipe.

DR. HENRY LING TAYLOR: It is very difficult to build houses on hygienic principles in the city on account of the high price of real estate. This is the fundamental trouble and the result is that there cannot be enough light or ventilation. I am becoming more and more convinced that nothing is more necessary for health than sunlight; it is a great purifier of bad air. According to my observations, sunlight, fresh air, and diet are the most important factors in hygiene, cleanliness being of less importance. Give dirty people sunlight and fresh air and they will usually keep well. I can confirm what has been said in regard to the ill-effects of over-heating houses: I have had to regulate this in a number of instances. Moreover furnaces and steam-pipes make the air peculiarly irritating on account of its dryness. The same degree of heat from an open fire-place does not have this effect and is not so injurious.

DR. WHITE: A paper of this character is of great practical value. The two great menaces to health in the present construction of houses are associated with the plumbing and heating. The former has been somewhat improved of late years, but the latter leaves much to be desired. Our hot-air furnaces are faulty. The influx of cold air is taken from the outer air and passed through a long wooden box which is never cleaned. This should be so constructed as to permit of the removal of dust charged with animal matter which accumulates there. Another source of danger is the water-tank which supplies moisture to the hot air. This is filled in many cases automatically and never cleaned, the result being that there is an accumulated deposit of mud and filth at the bottom from which a poisoned vapor is sent through the house. This may be the cause of what we call "grip" which prevails in the autumn months, when furnaces are first put in use, and continues more or less until warm weather is established. This also doubtless accounts for much of our New York malaria. The author has covered the ground very fully in regard to the improvements which should be made in our dwellings and most if not all of his recommendations find in me cordial endorsement.

DR. J. H. FRUITNIGHT: The hygiene of habitations has a great deal to do with the health and happiness of the people. Sunlight is essential but we are robbed of it by tall buildings. Our houses are imperfectly ventilated, especially the halls which, as a rule, are not ventilated at all. It may not be out of place to refer to the most brilliant and striking example of the benefit of sanitary control which is afforded by Dr. Wood in his report on the present sanitary condition of Santiago. As may be imagined, the conditions of living were very primitive there. Cess-pools are used and when these are cleaned, the contents are carried through the dwellings. By the enforcement of sanitary measures, the death-rate of the population fell from nearly 100 per day in the early part of August, 1898, to 30 or 40 a week in January, 1899, and in the middle of February, 1899, there was only 1 death in a period of nine days.

DR. ROBERT A. MURRAY: In regard to faulty plumbing, a great deal of this is due to the fact that not one-tenth of householders understand *why* things should be done in a certain way. The open-plumbing of to-day is a great improvement over the old method. The mortality in the upper part of this city is 4 or 6 per 1000, and very much higher than this in the crowded tenement-house districts where it is 26 per 1000. This is higher than the death-rate of London, Glasgow, or Birmingham, and is probably due to the fact that we do not control the occupants of our tenement houses, consequently they disregard cleanliness and other sanitary regulations. Our apartment-house are also conducive to ill health, for the reason that it is very difficult to properly ventilate them; they are usually overheated. All the rooms being on one floor it is impossible to ventilate one room without ventilating the others, consequently fresh air is dispensed with. In the ideal house, the sleeping apartments should be far removed from those occupied during the day—better on another floor. I am convinced that the mortality in hospitals would be lower if it were possible to remove the patients and thoroughly ventilate the wards; so that wards could be used in rotation.

DR. J. LEE MORRILL: Infectious gases may enter a house and cause disease. In a case which came under my observation the patient, a little boy, developed fever of a remittent type with persistent vomiting. A diagnosis of acute tubercular meningitis had previously been made by a prominent physician who is now dead. As the illness seemed to me to be of malarial origin I advised the administration of quinin. This was retained and the boy soon recovered. At my suggestion, the house was searched for defects in plumbing and it was found that the cement which surrounded the sewer-pipe in the cellar-wall had crumbled away, leaving a space through which foul-air from a break in the sewer some seventy-five or a hundred feet away was admitted to the cellar and thence to the rest of the house. This opening was closed and the boy has since remained well.

DR. LEO, in closing: As to the statement made in the paper in regard to tuberculosis being caused by damp cellars, I can only refer you to the authority I quoted—the Ninth Report of the Medical Officer of the Privy Council of Great Britain, Sir George Buchanan, in which he states they carefully investigated the causes of tuberculosis, and that the disease may be produced by moisture under dwellings. Such was their conclusion then.

As regards plumbing, I am pleased to be able to affirm that good American plumbing is the best to be found in

any part of the world. I have reached this conclusion after investigations made in the large Continental cities. My friend, the late Colonel Waring, was of the same opinion. The sewerage of New York, however, is bad. Most of the sewers were built during the days of the Tweed ring by contractors who grew rich but did the work badly. In some places the pipes run up hill, whereas there should be a slight descent or fall toward the outlet. The result is that only the fluid on top runs out while the solid part of the sewage remains in the pipe. It would cost millions of dollars to sewer New York properly.

Meeting of May 17, 1899.

FRACTURE OF THE NECK OF THE FEMUR; OSTEOMA OF THE FEMUR; GROWTH OF THE HUMERUS.

DR. JOHN F. ERDMANN: I have here some skiagraphs which are of exceptional interest. The first was taken in the case of a child, eleven years of age, who had sustained an injury of the right hip by falling on the pavement during a snow-storm. After this fall she was unable to walk. She was put to bed and seen by a physician who said that she had merely strained herself. I saw her about twelve weeks after the injury. There was then a large exostosis of the right hip and it was a question whether the case were one of fracture of the neck of the femur or a diastasis. As you see, the skiagraph shows very plainly that fracture of the neck had taken place. There is now thirty or forty degrees of flexion, with very fair rotation, and about three-quarters of an inch shortening.

The second skiagraph shows a so-called ossifying-hematoma or osteoma of the right femur. A peculiar feature of the case is that the patient, a physician twenty-nine years of age, has a number of these exostoses on various parts of the body. The tumor of the femur was first noticed about twelve years ago a little above the knee joint. There was a slipping and popping of the muscle as it slipped over the growth which was then about half an inch long and is now about one and a half inches long and one inch wide. I also found exostoses on the bones of the right forearm, one on the left ulna, and one on the left femur. The skiagraph only shows the one on the right femur. The growth is on the outer side of the thigh, although they commonly appear on the inner side and are known as "riders' bone."

The third skiagraph shows a bony growth of the right humerus in a man aged twenty-nine years. It was first noticed when he was twelve years old and grew very little during the succeeding ten years, but during the last three years it has increased rapidly in size. The tumor is at the upper part of the humerus and now measures nineteen inches in circumference, five inches in transverse diameter, and seven inches in length. It has the external appearance of a malignant growth, the veins are enlarged, but there is no involvement of the skin or muscular tissue. From the history I should say that it was originally an osteochondroma or ossifying hematoma which perhaps is now taking on a malignant change. The patient consulted me because of the pressure on the chest in the axillary line caused by the growth. The function of the arm is not interfered with.

In the second case the growth is also of long standing, and the question arises as to the possibility of there being a malignant outcome. It is generally believed nowadays that no matter how benign a tumor may be, it is best to remove it; yet, when I showed this case to the Surgical Society with a view to raising the question as to the advisability of operating, the concensus of opinion was to leave it alone so long as the growth did not give pain or interfere with function.

DR. HENRY LING TAYLOR: I am much interested in cases of fracture of the neck of the femur in young people, and recently showed two boys before the Orthopedic Section of the Academy, in whom the fracture resulted from slight injury in the sixteenth year. Since then I have seen what I at first believed to be another case occurring in a boy of sixteen years, but am now of the opinion that it is one of coxa vara associated with traumatism. It may be extremely difficult to differentiate between the two. As Dr. Whitman, who has done excellent work in this direction, has pointed out fracture of the neck of the femur is practically a traumatic coxa vara. Dr. Whitman has ascertained that the shortening in these cases almost invariably increases as time goes on. This is due to the fact that union takes place at a lower angle than is normal and the result is that the neck of the femur is not able to bear the weight of the body and yields under it. A shortening of from half an inch to an inch may in the course of several years increase to two inches or more with a corresponding aggravation of the limp. This is a very practical point. The cases should be followed up and watched and treated with a hip-splint like cases of non-traumatic coxa vara. Dr. Whitman is also of the opinion that these are cases of true fracture and that diastasis of the femur is very rare. The skiagraph shown this evening confirms all the points made by Dr. Whitman, except, of course, the increasing shortening which will no doubt be noted later on.

The third skiagraph reminds me strongly of a case seen a few weeks ago at the Hospital for Ruptured and Crippled occurring in a boy eleven or twelve years of age. The tumor was in the femur, just below the neck. It was of the size of an orange and had existed for about a year without causing any discomfort. Unfortunately the case passed from under observation.

CASE OF LUPUS TREATED WITH SCHWEINFURTH'S SERUM.

DR. ROBERT H. GREENE: I have under observation at the City Hospital a young man suffering from lupus. The disease is extensive, covering nearly all the body, has existed for years, and is steadily increasing. Various methods of treatment have been employed without benefit. Acting upon the suggestion of Dr. Fordyce, I procured from Washington a bottle of the new tubercular serum. It is a horse-serum made by Dr. Schweinfurth, the bacteriologist of the Department of Agriculture and differs from Koch's tuberculin which is an extract. This serum is manufactured for tuberculosis in

the same way the antitoxic diphtheria serum is prepared. I began giving the patient injections of 2 minims of the serum and gradually increased the amount until now he is getting 20 minims daily. He has had no other treatment and no special diet, but strange to relate the disease is getting better. The patches show a tendency to heal from the center toward the periphery. In this respect the effect is different from that which follows the use of tuberculin in similar cases, in which case a red zone is formed about the patch and the healing is from the periphery toward the center, the use of tuberculin, in other words, being attended with a local reaction as well as a general one as shown by the chills, fever, etc. Accompanying its use with the antitoxin tubercular serum in the quantities above described there is apparently no reaction either local or general.

CHANCRE OF THE LIP IN A YOUNG CHILD.

Dr. L. Duncan Bulkley: An interesting case came to me the other day from Dr. E. L. Cocks in which there were external manifestations of syphilis in a child seven months old. The initial lesion was a chancre of the lip which was apparently traced to the infected nipple of a nursing-bottle. Upon the trunk was a fully developed macular syphiloderm which had appeared three or four days previous. The disease could hardly have been congenital, for the child was well nourished and magnificently developed. The mother was healthy. The chancre was half an inch in diameter, not very sharply defined nor very characteristic; it exuded moisture. The glands under the jaw were enlarged. The child being bottle-fed the theory is that he was infected by some one who tasted the contents of the bottle to see if the food was of the proper temperature—a most reprehensible habit. I have never before seen acquired syphilis in a child so young, although plenty are reported in the literature.

Dr. Robert A. Murray then read the paper of the evening, entitled

DYSMENORRHEA.

The author said in part: Dysmenorrhea, or painful menstruation, through its regular recurrence and dire effects in depreciating the vitality, limiting the usefulness, and destroying the happiness of women, is a subject demanding constant study. Frequently looked upon as a necessary consequence of the menstrual function, palliative measures in the shape of narcotics, stimulants (particularly alcoholics) are administered to the young as well as the adult female until habits of life are formed which often result in wrecked lives and fearful domestic tragedies.

Clinically the condition may be discussed under the headings of (1) congestive or inflammatory; (2) membranous; (3) obstructive or mechanical, and (4) neuralgic, and each variety may be complicated by acute or chronic disease of the tubes, ovaries, or uterus. Ovarian dysmenorrhea, as usually described, is really ovarian or tubal disease complicating one of the foregoing forms.

Theoretically the treatment of all forms of dysmenorrhea may be divided into that which is directed toward easing the pain and causing the flow to be free and which usually relieves all the symptoms, and that which is instituted between the periods to remove the cause. Congestion of the uterus may be relieved by the use of heat applied as a foot-bath, the feet being immersed for twenty minutes in warm water the temperature of which is gradually increased. The hot sitz-bath is of value, as are also hot fomentations to the abdomen, with or without rubefacients, such as turpentine or spirits of camphor. Dry heat in the form of the hot water-bag may also be applied to the lower lumbar region and the inner surface of the thighs. Warm drinks may be administered but the use of alcohol in any form is to be deprecated. In cases in which arterial tension is high, aconite, pulsatilla, and veratrum viride, in small doses frequently repeated, are very efficacious. Apiol in capsules and salicylate of soda, if a rheumatic diathesis exists, are often effective. Most of the coal-tar products relieve the pain, particularly if they be combined with codein in half-grain doses. Morphin and other preparations of opium are occasionally necessary but should be employed most cautiously. In full-blooded women the intense uterine congestion may produce a marked disturbance of the circulation. In such cases puncturing of the cervix will give relief and bring on the flow. In a few cases in which I have found the patient delirious with pain and in one in which there was marked congestion of the brain and the patient was in a comatose condition, great relief followed a free bleeding from the arm.

In cases of obstructive and membranous dysmenorrhea, after tonic and hygienic treatment have been employed without avail, a local examination should be made to ascertain the cause of the condition. Here I would most earnestly condemn the indiscriminate employment of vaginal examination in young girls without having previously exhausted all hygienic and medicinal means of relieving their dysmenorrhea. Before resorting to the vaginal examination, rectal touch should be employed to determine the size and position of the uterus and appendages. To the educated hand this method of examination is as satisfactory as that made by the vaginal route. If an operation seems indicated this and the preliminary vaginal examination should be done under ether to avoid shocking the susceptibilities of a young girl. Stenosis of the cervix, particularly at the internal os, and endometritis are among the most common causes of this form of dysmenorrhea. Dr. Sims advised and for a time practised splitting the cervix by bilateral incisions extending up to and including the internal os for the relief of this condition, but the operation is somewhat dangerous, frequently inefficient, and leaves the patient with a lacerated cervix. The introduction of graduated sounds, followed by intrauterine applications of iodin, carbolic acid, nitrate of silver, and other caustics, has also been employed but the method is not only ineffectual but is attended by the danger of infection and of setting up pelvic peritonitis. Electricity has also been used and one cannot deny that the cervix uteri can be dilated almost painlessly by means of graduated sounds attached to the negative pole with the positive pole upon the abdomen and the application

of the galvanic current—from five to fifteen milliamperes—for five minutes at frequently repeated sittings. The faradic current will also relieve the symptoms. My experience with electricity, however, has been disappointing because the results obtained have not been permanent, and it is my belief that this is due to the caustic action of the zinc pole upon the endometrium. The best method of treating these patients is by over-distention of the cervix by means of a manual dilator, a thorough curettage, and an application of carbolic acid. The operation should be done under anesthesia and should be preceded for a short time by the employment of boroglycerid tampons. The curettage should be preceded and followed by an intra-uterine douche of hot sterile water. If proper precautions are taken the dangers are *nil*

The neuralgic variety of dysmenorrhea is difficult to treat. General treatment should be instituted; but little else can be done. The patients seem abnormally sensitive to pain and to the worries and cares of life, and slight shocks to their emotional nature cause great aberrations in their vital functions. Locally little is to be made out but a sensitive or prolapsed ovary or a slightly atrophied or congested uterus. But even after these abnormalities have been corrected, the patients still complain. It seems to me that what such a patient most needs is not rest but a healthful occupation which would divert her mind. It is important that this condition be recognized lest the physician be persuaded to prescribe anodynes to such an extent that a habit is formed.

DR. SIMON BARUCH: The treatment mentioned by the author is the same which I have pursued for many years and, I am sorry to say, with very poor results. I am very pessimistic in regard to the cure of dysmenorrhea. There is only one class of cases which is amenable to treatment by tonics, *viz.*, that which is composed of overworked girls who have damaged their cortical cells by mental or physical strain. I am not a believer in the operative treatment of dysmenorrhea. Of the cases in which operation has been done in my clientele, I do not think I have ever seen one patient cured. I myself have dilated the cervix and have had my gynecological friends do it, and once have been obliged to consent to removal of the ovaries to relieve pain which was intolerable, but the results have been unsatisfactory. In the case in which oophorectomy was performed, while there is, of course, no more dysmenorrhea, the patient is still a neurotic wreck in spite of electricity, hydrotherapy, change of scene, etc.

I am heartily in accord with the author in what he says about the abuse of the vaginal examination in young unmarried women. For a great many years I was physician to a large institution in which many female teachers were employed. These poor girls feeling a little hesitancy about applying to me for relief from their ills, in some instances consulted our female colleagues who do not seem to have the same repugnance which I have to making a local examination in young girls, and after being treated with tampons, etc., they would eventually come to me for treatment of their anemic condition. In these cases tonic treatment was followed by the most beneficial results.

DR. ROBERT NEWMAN: Among the causes of dysmenorrhea the author has mentioned surf-bathing. In my experience I have found that bathing in salt water during menstruation does no harm, but that bathing in fresh water in many cases causes suppression of menstruation. I am glad to hear the author make favorable mention of electricity in the treatment of dysmenorrhea. I know of cases in which it has done wonders. In cases in which the uterus was not properly developed, the growth of the organ has been stimulated by galvanism and a common cause of dysmenorrhea removed. Again, neuralgic ovaritis, another cause of dysmenorrhea, is relieved by an external and internal combination of galvanism, and in some cases the high tension faradic current has been known to cure dysmenorrhea, acting as an analgesic.

DR. J. BLAKE WHITE: I can corroborate what the author has said in regard to dysmenorrhea being a symptom and the necessity of seeking for its cause. There is hardly a subject in medicine which calls for so much thoughtful sympathy for the patient and so much palliative treatment with judgment for its relief as dysmenorrhea. I have seen cases in which benefit followed the administration of the coal-tar preparations; others in which these drugs alone would not give relief, but would act well when combined with belladonna, camphor, and hyoscyamus. In some troublesome cases in which other remedies failed relief followed the administration of a warm enema, and where there is a tendency to constipation I have advised, with decided beneficial results, the administration of a full warm enema on the approach of menstruation and for the two or three succeeding days of its continuance.

Not infrequently, as we all know, a dysmenorrhea results solely from anemia and is promptly relieved by judicious ferruginous medication. I have found that some of these patients are more speedily and satisfactorily relieved from subsequent attacks of dysmenorrhea by different preparations of iron—sometimes combined with arsenic. Of course these cases are not due to local conditions which require other and more radical treatment.

DR. A. M. JACOBUS: It has always seemed to me that chronic dysmenorrhea, like headache, is difficult to discuss, and still more difficult to treat. According to my experience the condition is usually met with in young women with infantile uteri. They commit some indiscretion such as cycling, horseback-riding, sea-bathing, dancing, or get their feet wet during menstruation, and, as a result, get endometritis, pelvic peritonitis, ovaritis, etc. Nothing short of some operative procedure, such as divulsion and uterine packing, will relieve these cases and it should be performed, if possible, before the appendages become involved. If these patients do not marry and bear children, they often become neurotic and hysterical and suffer to the end of their menstrual life. Another form of dysmenorrhea results from a chronic endometritis following a miscarriage, especially when the latter has been induced. Sepsis after childbirth is also a cause of chronic dysmenorrhea. I have seen cases in which dilatation did good and others in which it had no effect. I

would not advise removal of the ovaries for dysmenorrhea any more than I would for insanity. Gynecologists know that most patients who suffer from dysmenorrhea also suffer from chronic constipation and chronic dyspepsia. Dr. Barker frequently said that constipation causes most of the trouble from which women suffer. In such cases, after treating the constipation and dyspepsia, I have obtained good results from the use of bromids, in 10- or 15-grain doses, three or four times a day before and during menstruation. The fluid extract of hydrastis acts well if the patient is inclined to flow freely, as do also the viburnum preparations. The high tension bipolar faradic current, given *per vaginam* two or three times each week, before and after the menses, is also a valuable remedy. In some cases tampons saturated with the commonly used boroglycerid mixture will give relief. If there is some displacement of the uterus which cannot be rectified by operation owing to the objection of the patient a pessary may be of benefit. Pessaries should not be used, however, if the uterus is bound down by adhesions or if the patient will permit surgical interference. Constitutional treatment should be employed as indicated.

In regard to the vaginal examination in young girls, I do not not advise it unless there is a very good reason. It is rarely necessary, for we can determine all we want to know by rectal touch.

Dr S. H. Dessau: As a general practitioner, I have met with these cases of dysmenorrhea and have my own views upon the subject. Gynecologists, as a rule, are too apt to consider dysmenorrhea as due to some cause which can only be removed by operation. This was impressed upon me recently by the case of a young schoolteacher. She was a delicate, neurotic subject and, as I found out later, a sufferer from chronic intestinal indigestion. She had dysmenorrhea for a long time and finally consulted a gynecologist who is connected with the Woman's Hospital who told her, after having made a vaginal examination, that an operation was imperative. She and her family were much shocked, and she was brought to me by her mother. I examined the young woman, since this had already been done, and found nothing abnormal and no indication for operation. I soon convinced myself that the girl was suffering from chlorosis and nothing more. I treated her for this condition, and in three months she had no more dysmenorrhea. This was two years ago, and she has had no return of the pain.

I regret that the author did not dwell upon the points of differential diagnosis. Some years ago I saw a very instructive case. The patient was a young married woman who for several months had suffered intense pain during menstruation. She was seen by a prominent gynecologist, now dead, who advised Battey's operation. She declined this, however, and passed through several other painful periods during which I saw her. One day she came to me with a phosphatic calculus which she had passed and after that she never had pain during menstruation. Strange to say, the patient had always referred the pain to the region of the right ovary.

Dr. Bulkley: I know dysmenorrhea only as a symptom, for I do not pretend to have any knowledge of what goes on inside of my patients, yet my experience in the treatment of this symptom has been so good that I fear no one will believe me. The discussion has gradually led up to what I am about to say, for Dr. Jacobus has alluded to constipation and Dr. Dessau to a phosphatic condition. I wish to speak of the condition of the urine. Some three or four years ago the late Dr. Etheridge of Chicago read a paper upon deficient excretion of the kidneys in women suffering from the diseases peculiar to them, showing that a sympathy exists between the kidneys and the uterus and appendages. In the following year I read a paper on deficient excretion and advised an alkaline treatment for these patients. Some years ago a young girl came to me with a bad acne of the face. She also suffered from dysmenorrhea, for which she had been treated, but without benefit. She was in a miserable condition, being so weak that she could not walk upstairs to my office. I placed her upon the following:

℞ Potassii acetatis . . . . ℥ i
Tinct. nucis vomicæ . . . ♏ ij
Ext. rumicis rad. fld. . . . ad. ℥ iv.

M. Sig. Teaspoonful in ⅓ tumbler of water half an hour before meals, beginning ten days before the expected period.

Before six months had passed she was not only able to walk upstairs, but could walk a mile from her house to my office and she had no more dysmenorrhea.

Again, the wife of a prominent physician in Brooklyn came to me for some skin affection. Among other things she spoke of her dysmenorrhea, which was so severe that the advisability of having ovariotomy performed had been about decided upon. I put her upon the alkaline treatment and employed an old-fashioned remedy which had a marvelous effect—a small blister, one-inch square, applied over the ovary, one week before and during the period—and in six months she was well.

Of the coal-tar products I have only found one of any service and that is antefebrin, in 5-grain doses at intervals of one hour when pain threatens, and later every two hours. It should be taken in hot water with a little whisky.

Dr. J. Riddle Goffe: I do not think that Dr. Bulkley's opinion in regard to the treatment of dysmenorrhea differs very much from that of most gynecologists. The treatment he employs is right in line with that which I believe is being used by all of us, except, perhaps, those extreme gynecologists who see nothing but what they think indicates operation. It is very largely a matter of hygienic management of the case and general treatment directed toward improving the nutrition and metabolism of the body.

I take a much more sanguine view of these cases than that which has been implied by some of the speakers and for this reason I do not hesitate to encourage patients to submit to come under treatment. The cases can be divided into two classes: (*a*) women who are married and have borne children and who have actual disease in the

pelvis, and (*b*) young women and girls. The former can and should be cured by removing the pathological condition in the pelvis which causes the dysmenorrhea. The latter are neurotic and anemic, as a rule, and what they need most is to have their digestion and assimilation put in order. Hygiene plays an important part here. I do not give drugs, except tonics, nor treat the patient as if the condition were a local one, but regulate the patient's life. The patients are usually women exhausted by social requirements, by study, or by hard work. The uterus is infantile because physical or mental overwork has prevented its development. There seems to be a strange law that if a woman passes through the period of adolescence without vitality to develop these organs sufficiently to perform their functions, the condition becomes chronic and requires an unusual degree of stimulation to relieve it. I order these patients to ride a horse or a bicycle, to row, and to do anything which will develop their general vitality and give them good blood. I am also a great believer in hot baths. I tell my patients to take a hot bath daily, as hot as they can bear it, and then spray themselves with cold water afterward. This makes the skin active. These baths should be kept up during menstruation. There seems to be a tradition that it is not safe for a woman to bathe while she is menstruating, but there is absolutely no reason why she should not; on the contrary, there is every reason why she should bathe, for a woman never needs a bath more than she does at that time. Surf-bathing, however, should not be indulged in. I also believe with Dr. Baruch that bathing stimulates the nerve-centers. If there is much pain during menstruation I make the patient keep very quiet. This is the plan upon which I treat these cases and I find that it works well. I have relieved many cases of dysmenorrhea by simply employing hygienic treatment. Sometimes, of course, I am not successful, in which case I insist upon a local examination and usually find some local cause for the painful menstruation. I do not believe in "obstructive" dysmenorrhea nor that the pain is due to an anteflexed and retroverted uterus; the latter is simply an undeveloped uterus.

DR. MURRAY, in closing: I have but little to add. I am fully aware of the deficiencies of the paper, which was not intended to be exhaustive, but merely suggestive. It is my belief that in my cases dysmenorrhea is due to deficient oxygenation. This explains why young girls who suffer from painful menstruation improve at once and with no treatment when they are taken out of school.

In regard to the blister over the ovary, this is a very old practice which was carried out with the idea that an ovaritis existed. It possesses, however, two advantages, *viz.*, it controls the circulation and keeps the patient quiet—the latter a most important point. It has the same effect in pleurisy.

I am convinced that surf-bathing is the cause of dysmenorrhea, and have known pelvic peritonitis to follow a sea-bath during menstruation. I am in favor of a warm douche, for the sake of cleanliness, during the period. Some women during the last day or two have as foul a discharge as that which accompanies sapremia after labor.

THERAPEUTIC HINTS.

For Non-Tubercular Bronchitis.—

℞	Potassii citratis	ʒ iv
	Suc. limonis	ʒ i
	Syr. ipecacuanhæ	ʒ iv
	Syr. simplicis q.s.ad.	ʒ iv.

M. Sig. One teaspoonful every two hours.—*Wood.*

A Liquid Vesicatory.—Fold a bit of gauze to the desired size, wet it with the solution given below and apply to the skin for ten or fifteen minutes. This is a convenient means of producing rapid vesication.

℞	Aq. ammoniæ concentrat.	Part i
	Ol. camphorat.	Parts ii.

M. Sig. External use.—*Gnéspin.*

For Aphthæ—It is stated by DE MIA that from observation of the results obtained by the use of a number of different applications in this disease he concludes nitrate of silver to be the most efficacious. If the aphthous spots be pencilled twice a day with a six-per-cent. solution a cure may be expected in four or five days.

An Antiseptic Powder.—The following combination of drugs is recommended by PICK:

℞	Hydrarg. chlor. corros.	gr. ⅓
	Ac. borici	ʒ i
	Ac. tannici	gr. x
	Sacchari lactis	ʒ i–ʒ iiss.

M. Sig. External use.

For Painful Dyspepsia. — The following preparation is prescribed either for simple painful dyspepsia or for that due to carcinoma:

℞	Cort. condurango pulv.	ʒ iv
	Aquæ	℥ x.

Macerate for twelve hours, then evaporate the decoction down to 5 ounces. Of this the dose is a tablespoonful three times a day.—*Friedrich.*

Or this:

℞	Cort. condurango pulv.	ʒ iv
	Ac. hydrochlorici	gtt. xv
	Syr. cort. aurant. amar.	℥ v.

M. Sig. One tablespoonful every two hours.—*Krauss.*

For Facial Neuralgia —

℞	Butylchloral. hydrat. } aa	ʒ iiss
	Spiritus }	
	Glycerini	ʒ v
	Aq. dest.	℥ iv.

M. Sig. One or two teaspoonfuls a day.—*Boucquillon-Simonsin.*

For Anorexia in Dyspepsia.—

℞	Sodii arsenitis	gr. i–ii
	Aq. dest.	℥ viii.

M. Sig. Two or three teaspoonfuls a day.—*Dubove* and *Rémand.*

ORIGINAL ARTICLES.

THE BACILLUS ICTEROIDES AS THE CAUSE OF YELLOW FEVER—A REPLY TO PROFESSOR SANARELLI.

By GEORGE M. STERNBERG, M.D.,
OF WASHINGTON, D. C.;
SURGEON-GENERAL, UNITED STATES ARMY.

I HAVE no time or inclination for controversial writing, but desire to state my position with reference to Sanarelli's bacillus as briefly as possible. In my paper published in the MEDICAL NEWS, November 13, 1897, I say:

If my bacillus *x* and the bacillus icteroides of Sanarelli are proved to be identical and this bacillus is demonstrated to be the cause of yellow fever, Sanarelli will deserve full credit for the demonstration, and I shall not be disposed to detract in the least from the praise due him for the success achieved as a result of his investigations. If, as he claims, he has obtained the final proof that this is the yellow-fever germ by producing the disease in man (five cases), as a result of the subcutaneous or intravenous injection of filtered cultures, I think we must accept these results as demonstrating the specific character of the bacillus in question. But without this final proof the demonstration would not be satisfactory, notwithstanding the pathogenic virulence of the bacillus when injected into several species of the lower animals. If it were constantly found in the blood and tissues of yellow-fever cadavers there would be little reason to doubt its specific character. But both my researches and those of Sanarelli show that, notwithstanding the most painstaking investigations, this bacillus has not been found in a considerable proportion of the typical fatal cases of yellow fever examined. . . .

In the series of cases studied by me secondary infections were extremely rare. The colon bacillus was found in a considerable number of cases, but usually in comparatively small numbers, and there is no good reason for believing that the fatal result depended upon its presence. But for the fact that in the second case studied by Sanarelli, his bacillus was present in considerable numbers in blood extracted from the finger of the patient the evening before his death, and also, after death, in the blood, spleen, liver, and other organs, it is quite probable that his attention would not have been attracted to this particular bacillus. In this regard this case is unique, both in the series of cases investigated by Sanarelli and in those studied by me; and if this is indeed the bacillus of yellow fever, it is evident that it is usually present in the blood or tissues of yellow-fever patients in very small numbers, or not at all.

In my latest publication (*Centralblatt für Bakteriologie*, May 13, 1899), I say:

The experiments which have been made under my direction in the laboratory of the Army Medical Museum in this city (Washington) have convinced me that the bacillus of Sanarelli and my bacillus *x* have permanent characters which distinguish one from the other and consequently that they are not varieties of a single pathogenic species. I am, therefore, obliged to admit that Sanarelli's researches give no support to the supposition, which for a time seemed to me to have a certain degree of probability, that my bacillus *x* is the specific cause of yellow fever. On the other hand, my researches give no support to Sanarelli's claim. My bacillus *x* was obtained by me, in small numbers, from about one-half of the yellow-fever cadavers examined by me in Havana. Sanarelli, using the same methods, found his bacillus in about the same proportion of cases and also, with one exception, in comparatively small numbers. Both bacilli are pathogenic for rabbits and guinea-pigs—Sanarelli's bacillus more so than my bacillus *x*. But experiments upon these animals fail to give any satisfactory evidence that either bacillus is the specific cause of yellow fever. Both bacilli when injected into the circulation of dogs (5 c.c.) produce vomiting, fever, a hemorrhagic gastro-enteritis with bloody discharges from the bowels, albuminous urine, necrotic changes in the liver, collapse, and death in a certain proportion of the cases.

With reference to Sanarelli's experiments upon man, I would say that the toxemia resulting from the injection of filtered cultures of his bacillus may or may not be identical with yellow fever in man. Further experiments would be necessary to determine this, and especially control experiments with the toxic products of other bacilli of the typhoid and colon groups.

In his first published paper Sanarelli says:

Sternberg thinks that there is probably a localized infection having its seat in the stomach.

In his recent paper in the MEDICAL NEWS, he says:

Primarily, Dr. Sternberg clung firmly to the idea that the seat of the specific virus of the disease was in the intestine. He seemed to have been of the opinion so commonly held by writers at that time, that a certain pathogenic analogy existed between yellow fever and Asiatic cholera, the discovery of whose germinal cause had been such a triumph only a short time before. The symptoms and intestinal lesions which are observed in the two diseases are certainly sufficient to impose such an opinion on the observer, if he looks no further.

These statements are entirely erroneous, and were

disposed of in my paper in the MEDICAL NEWS above referred to, in which I say:

This is a mistake. I have advanced the hypothesis that the germ of yellow fever may perhaps be located in the alimentary canal, as is the case in cholera, and that the symptoms result from the absorption of a very potent toxin produced by it. But this is only a suggestion, and I know of no evidence indicating that there is a localized infection of the stomach. I have carefully studied many stained sections of the walls of the stomach, and have never found any evidence of a localized infectious process, although in a certain proportion of the cases there is evidence of inflammation, as shown by the presence of an unusual number of leucocytes in the submucous coat.

The small intestine commonly contains more or less black matter, either fluid and resembling that found in the stomach, or mixed with mucus and smeared over the mucous coating, especially of the ileum. This, no doubt, comes partly from the stomach, but in other cases is due to passive hemorrhage from the mucous membrane of the intestine itself. This membrane presents arborescent patches of congestion, or portions of the canal may be uniformly red from hyperemia of the mucous coat; the color varies from a pale-red to a reddish-brown, and is usually more marked in the lower portion of the ileum than elsewhere. The large intestine occasionally presents similar arborescent patches of congestion, but it usually has a normal appearance. Finally, we may say that the attention of pathologists has heretofore been so largely taken up with the pathologic histology of the organs which present the most notable changes—liver and kidney—that the histology of the alimentary canal has been somewhat neglected, and further researches in this direction are desirable upon material obtained at the earliest possible moment after death.

It was not until after my failure to find any specific micro organisms in the blood or tissues that I devoted special attention to the alimentary canal. In my original report (1890) I say:

My first five autopsies, made in 1888, gave a negative result. In Case VI., autopsy four hours after death, colonies of two different kinds were obtained in cultures from the blood, liver, and kidney. One of these was my bacillus *a* (*bacterium coli commune*).

Again, in Cases VII. and VIII., the result was negative; but in Case IX., in which the autopsy was made five hours after death, numerous colonies of bacillus *a* developed in my cultures from the blood, liver, and kidney. The next case in which I obtained micro-organisms from the blood was in No. XV., Havana, 1889. In this case a few colonies of a different bacillus were found.

In Case XVIII. I again obtained a few colonies of bacillus *a*.

Case XIX. gave a negative result, and in subsequent autopsies I did not collect blood from the heart, inasmuch as the material obtained from the liver always contained a considerable quantity of blood and would show the presence of micro-organisms if they were to be found in the general circulation.

A summary of these results shows that I have obtained micro organisms in my aerobic cultures as follows: In blood from the heart, four times in nineteen cases; in the liver or kidney or both, thirteen times in forty-three cases.

It will be noticed that the micro-organisms most frequently encountered were non-liquefying bacilli, my bacillus *a* and bacillus *x*.

We are, therefore, able to assert in the most positive manner that the blood and tissues of yellow-fever cadavers do not contain aerobic liquefying organisms, unless by rare exception, and can definitely exclude the micrococcus of Freire and the tetragenus of Finlay from consideration as possible agents in the etiology of this disease, as both of these grow readily in the culture-medium used in these investigations and both liquefy gelatin.

The non-liquefying bacilli found in a certain proportion of the cases are not in sufficient numbers or sufficiently constant to give support to the view that they are the specific cause of the disease, and the fact that they are not found in a considerable number of typical cases is sufficient reason for excluding them as being directly concerned in its etiology by reason of their presence in the blood and tissues. But we may suppose that they have their proper habitat in the alimentary canal and that the morbid phenomena are due to a toxic ptomain, produced in this situation. Under this hypothesis the occasional presence of these bacilli in the tissues is to be regarded as accidental and as resulting from the emigration, during the last hours of life or post-mortem, of micro-organisms from the intestine, and we have to ascertain whether one of the bacilli found most commonly in the tissues or any other micro-organism present in the alimentary canal is the specific agent we are in search of.

I may remark here that if Sanarelli's bacillus is the cause of yellow fever and is to be found in the blood it could not well be absent from the alimentary canal in fatal cases as these almost invariably show the presence of disorganized blood both in the stomach and in the intestine. But Sanarelli asserts that his bacillus is not found in the contents of the intestine. In my paper in the MEDICAL NEWS I say: "I think it would be very unfortunate if, upon the strength of Sanarelli's negative results, sanitarians should neglect to disinfect the excreta of yellow-fever patients."

In support of his mistaken inference that I have looked upon the intestinal tract as the seat of the infection, Sanarelli says:

That Dr. Sternberg held this opinion is clear, since in his report to the United States Government[1] in his official capacity he submits as one of his conclusions a suggestion for the treatment of the disease by disinfection of the intestinal tract, an alkaline solution of bichlorid of mercury of 0.02 per cent. being employed for this purpose.

[1] "Report on the Etiology and Prevention of Yellow Fever," p. 85, Washington, 1890.

This erroneous prejudice as to the pathogenetic mechanism of the disease was sufficient without doubt to influence the whole course of his researches. For it is evident that Dr. Sternberg yielded to the preconceived notion at that time so generally accepted, that it would be possible to isolate from the contents of the intestinal tract a microbic form that would be constant for the disease.

Sanarelli is not the only one who has made this mistaken inference, which, however, I have repeatedly corrected. In my original report I say:

My principal object in suggesting the formula was to test a decidedly alkaline treatment from the outset of the attack, with a view to relieving the gastric distress and acid vomiting, which is a prominent feature in cases treated by the expectant method, and also to render the highly acid urine neutral or slightly alkaline, in the hope that the secretion would be more abundant and the tendency to suppression diminished. The treatment appears to meet these important indications; and, without in any sense being "specific" to save life by preventing those structural changes which give rise to passive hemorrhage from the stomach and suppression of urine—two symptoms which present themselves in a majority of the fatal cases.

Bichlorid of mercury in a comparatively small amount was added to the formula, not with the idea that it would to any extent destroy pathogenic micro-organisms in the intestine, but as an antiseptic, which might be useful in preventing fermentative changes in the stomach, which would, perhaps, be favored by the free administration of an alkali. The idea has also occurred to me that the specific germ may possibly find a suitable nidus in the acid secretions of the stomach, and in this case the administration of an antiseptic in combination with an alkali would be the most rational treatment. Still I have not given much weight to this idea.

Sanarelli reproaches me with not being willing to yield to the evidence in favor of the specific etiological rôle of his bacillus. I am not influenced in my scientific conservatism by any feelings of jealousy and shall be ready to do full honor to the discoverer when the discovery is definitely established. At present I cannot admit this for the following reasons:

First, Sanarelli's bacillus grows readily in the culture media employed by me in my researches, but in nineteen typical cases of yellow fever in which I introduced into such media blood from the heart of yellow-fever cadavers, this bacillus was not present, the cultures remaining sterile in fifteen. In three of the four cases in which a growth occurred I identified the bacillus found as bacillus coli communis (my bacillus *a*). I strongly suspect that some of those bacteriologists who claim to have found Sanarelli's bacillus have mistaken for it one of the varieties of the colon bacillus.

Second. In my experiments material from the interior of the liver and kidney, containing blood and crushed tissue elements from fresh cadavers, was added to culture media in which Sanarelli's bacillus readily grows, but I obtained a negative result (cultures remained sterile) in 30 out of 43 cases.

Third. Sanarelli's bacillus is fatal to guinea-pigs and rabbits when injected subcutaneously in very minute doses. In my experiments blood from the heart and crushed liver tissue from the fresh cadaver failed to kill eight out of ten guinea-pigs and seven out of eight rabbits experimented upon. I admit that the value of these experiments is impaired by the fact my laboratory facilities did not permit me to keep these animals under observation as long as was desirable.

Fourth. The experiments made by Drs. Reed and Carroll at the Army Medical Museum show that Sanarelli's serum in high dilutions (1–100,000) causes arrest of motion and typical agglomeration (Widal reaction) of the bacillus of hog cholera: also, that serum from an animal immunized against hog cholera, in high dilutions, causes arrest of motion and typical agglomeration of Sanarelli's bacillus; also, that cultures of Sanarelli's bacillus fed to pigs cause the death of these animals, and that the typical lesions of hog cholera are found in their intestine.

Fifth. The blood-serum of yellow-fever patients or of convalescents from this disease does not give a marked Widal reaction with Sanarelli's bacillus, although the blood of an animal immunized by the injection of cultures of this bacillus does give the specific reaction in high dilutions.

Sixth. So far as I am informed the results obtained in the use of Sanarelli's antitoxic serum do not give support to his claim to have discovered the specific germ of yellow fever.

In a letter dated January 20, 1899, my friend Dr. J. B. de Lacerda of Rio de Janeiro, says:

The serum of M. Sanarelli has failed here in Brazil. The results of the experiments which he made at San Paulo have not recommended the employment of this serum. It is neither preventive nor curative.

In a paper recently published in the *New Orleans Medical and Surgical Journal* Dr. P. E. Archinard reports a negative result from the use of Sanarelli's serum in ten cases. He says:

From the above cases, which limit our experience with the anti-amarylic serum of Sanarelli as a curative agent in the human being attacked with yellow fever, we are forced to conclude that this agent, in our hands, has shown no curative powers whatsoever, none of the important and dangerous symptoms of the disease having

been in any way mitigated or prevented by its administration.

Drs. Reed and Carroll are now preparing a report of their extended researches, which have been going on at the Army Medical Museum during the past two years. This report will be published in due time and will give full details as to the experimental evidence upon which they base their conclusion that Sanarelli's bacillus is a variety of the bacillus of hog cholera.

Finally, I would say it appears to me at the present time that, like the colon bacillus and bacillus *x*, the bacillus of Sanarelli is a pathogenic saprophyte which is present occasionally and accidentally in the blood and tissues of yellow-fever patients, and that its etiological relation to this disease has not been established. If, however, the results reported by Drs. Reed and Carroll can be shown to be based upon erroneous observations, I shall be ready to revise my opinion. Truth is mighty and no doubt in the end will prevail.

SOME FALLACIES IN THE MODERN TREATMENT OF NOSE AND THROAT DISEASES.[1]

By DUNBAR ROY, M.D.,
OF ATLANTA, GA.;
CLINICAL PROFESSOR OF EYE, EAR, NOSE, AND THROAT DISEASES IN THE ATLANTA COLLEGE OF PHYSICIANS AND SURGEONS; OCULIST AND AURIST TO THE GRADY HOSPITAL.

SPECIALISM seems to be the order of the day, and not unjustly so. It has its advantages and disadvantages. A man who confines his practice to a certain region of the body is certainly more familiar with pathologic changes in this region than the man who but rarely has such cases come under his observation. The man who treats 100 cases of typhoid fever in a year is certainly more capable of making a clear diagnosis and instituting appropriate treatment than one who sees five cases of the disease. In other words, the larger the experience of any man is in a special line of work the more expert he becomes in that work. But the tendency of the specialist is to become narrowed. Most of them will deny this allegation, nevertheless it is true. I feel that I may be permitted to speak freely since my own daily work for the last six years has been confined to a limited portion of the human anatomy, and I am better able to see my own mistakes and those of my colleagues in the same field of labor. A man can never become a successful specialist until he has become familiar with the whole human frame and the various diseases to which man is heir. This means, of course that no man is prepared to be a specialist who has not been in practice for a number of years, or at least served as interne in a large general hospital. A man, to be a successful practitioner or specialist, must be broad-minded, and broader still must be his knowledge. He who limits his study exclusively to one portion of the human anatomy can never be successful. One organ of the body is but a small portion of the whole, nor does it functionate as a distinct entity. Every part is dependent upon some other part and it requires the harmonious action of the whole for the well-being of each single member. Hence, the truly successful specialist is he who looks beyond the region where his work lies and takes into consideration the relationship existing between every portion of the human organism.

The specialism limited to the diseases of the eye, ear, nose, and throat is perhaps the most popular of all to the young graduate in medicine. He sees in it the El Dorado of long-hoped-for fortune. It is the specialty which, to him, requires the least amount of study and in which his mistakes will be the least noticeable. The question of life and death is not usually involved and, with the exception of the eye, the work is done in closed cavities obscured from the patient's scrutinizing gaze,and he is, therefore, to a great extent, shielded if he makes a mistaken diagnosis. This state of affairs brings specialism into disrepute, simply because this or that patient has one of this class of men who, perhaps, has not only failed to give relief, but has done actual harm. The great trouble to day is that men go into special work who have not properly qualified themselves to treat the whole human system. They see no further than the little organ to the treatment of which they expect to devote their life. They recognize no dependence of one pathologic condition upon some other diseased state in another portion of the body. In no specialty, I believe, are men found who are less worthy of the name "specialist" than those who set themselves up to treat eye, ear, nose, and throat diseases. It is true that the treatment of this class of diseases appears easy, and perhaps it is so, but the great question to be determined is, What is the appropriate treatment? It is one thing to treat and quite another to treat properly. The nose specialist who furnishes his office with a set of spraying apparatus, a nasal saw, a galvanocautery, and a wire-snare believes himself to be thoroughly prepared to treat all nasal diseases, and in his mind the idea is well fixed that there are no diseases of the nasal passages which cannot be cured by this outfit.

I wish now to discuss what I believe to be some of the fallacies in the treatment of nose and throat diseases. I mean by fallacies the false recognition of pathologic conditions and the wrong remedy for the condition when it is recognized.

On the Use of Sprays.—No throat and nose spe-

[1] Read at the annual meeting of the Georgia Medical Association, held at Macon, Ga., April 19–21, 1899.

cialist feels that he can be considered as such unless he has a condensed-air apparatus in his office, worked either by hand- or by water-power. Sprays in the nose, provided the substance sprayed is the correct medicament, are exceedingly valuable in a large number of cases, but their indiscriminate use in every case is often exceedingly injurious. Even in the few years of my practice I have found that there is such a thing as the "spray-habit," which is brought about largely by specialists who consider that it is necessary for patients to come to their office every day or every other day and be sprayed, until it not only becomes a habit with the patient, but a mercenary habit with the physician. A "spraying out" makes a patient feel better temporarily and in one in whom the nasal chambers have been closed the sensation of opening up is delightful, but unfortunately, there is a reaction and the opened condition does not last. There are two fallacies connected with the use of sprays, more especially in the nose, which I have found to exist with undue frequency among rhinologists. The first is that the pressure used for atomizing the liquids is frequently too strong and the result is that the mucous membrane is injured and, therefore, harm instead of benefit is the result. The mucous membrane in the nose is tender and sensitive, and for this reason the force of any spray should be well regulated. Some patients require a stronger spray than others; as, for instance, in atrophic rhinitis, in which condition irritation of the mucous membrane is considered by some as the rational therapy. But with this exception I know of none. In the second place it has become an almost universal habit to use, without proper discrimination, some oily product as the base of all spray medicaments, in contradistinction to watery sprays formerly used. There are patients who require the use of both, and perhaps frequently at the same time, yet both have their sphere of usefulness.

The "spray-habit" comes most frequently from the use of menthol in the oily menstruum, producing that cool sensation in the nose which is so delightful and exhilarating to the patient. The use of a spray primarily is supposed to be for its cleansing properties, and afterward, but very secondary, for its soothing and stimulating qualities. Now it is a well known fact that discharges from the membrane of both the nose and throat are watery or mucoid in character and, therefore, will not mix with oil. How utterly unscientific is it, then, to try and cleanse the nasal mucous membrane with spray material which is oily. Logically, watery cleansing solutions should be used first and then oily ones, should the case demand it. I hold that spraying of the nasal chambers is never justifiable unless there is catarrhal discharge from the membrane readily recognized on anterior rhinoscopic examination, or when there is an accumulation of mucus coming from some of the contiguous cavities such as the frontal or ethmoidal sinus, or the maxillary antrum. In such cases the spray must be alkaline and watery, for the endeavor should be to simply cleanse the membrane, and such a solution alone will do it. Oily sprays are too frequently used for this condition, and the result is the patient gets the "spray habit" and exceedingly dry nasal chambers. Oily sprays are useful in their place and especially so in acute inflammatory conditions of the membrane of the nose and throat, but in chronic conditions of the same membranes they are almost useless.

The Use of the Electrocautery. — This is an exceedingly useful instrument in the domain of rhinology and laryngology but like sprays it has been abused. In my earlier practice I used the electrocautery ten times where I now use it once. Not that it is not now serviceable, but then I used it for nearly every little enlargement which I found. Its great value in the nose is for the reduction of true hypertrophy of the membrane covering the turbinates when this is pouring out an unhealthy discharge or is so blocking the lumen of the nasal cavities as to prevent thorough passage of air. I say true hypertrophy, since that hypertrophy in the nose which disappears under the influence of cocain is not hypertrophy but nothing more than passive congestion or stasis. In the latter case it is foolish to use the electrocautery, for here is a condition in which the cause must be treated, and in a great many cases it is far removed from the nasal cavities. It may be a reflex phenomenon from various constitutional disorders, such as anemia, chlorosis, torpid liver, ovarian and uterine disease, heart lesions, disease of the kidneys, chronic constipation, and from nearly every constitutional dyscrasia.

If the specialist has had no experience in general medicine he never sees beyond the nasal cavities, but will use topical applications ad nauseam, to the weariness of both the patient and himself. Equally as important as when to use is the manner of using the electrocautery. I have seen many nasal cavities which have been made far worse by the use of the cautery than had it not been used at all. The trouble in many cases has been due to the too extensive use of this instrument with the result that the inflammatory reaction set up at the point of cauterization has been so severe that a dense band of cicatricial tissue extends clear across the lumen of the nasal cavities, and thus acts as a barrier to free respiration. There is no excuse for the production of this

condition if the physician has learned the proper technic and knows when the cautery should be used. "A good man can sometimes be made the unworthy instrument for the production of evil," and only too well can this aphorism be made to apply to the electrocauterist.

Another error frequently committed is the too frequent removal of enchondromata or cartilaginous spurs and exostoses or bony spurs from the nasal septum. When the full-fledged nose specialist opens his office for the reception of patients the first thing he does is to brandish his bright metallic saw and remove every little excrescence he finds on the nasal septum. Even now I can feel the enthusiasm which coursed through every fiber of my being when in the first few years of my practice I could discover a septal spur. But unfortunately some of my patients were made to suffer for this enthusiasm. With ripened experience I find that fewer spurs should be removed from the septum, and only in those cases in which other well-recognized methods of treatment have been tried and failed. My reasons for this are that after a spur has been removed from the nasal septum scar tissue is necessarily left as a result and this will always give the patient a point where mucus and scabs will form, to his constant annoyance, sometimes proving more annoying than the slight obstruction itself. It is very alluring to the young specialist to perform this little operation and thereby pocket a nice little fee, for the hope of material gain is sometimes not the only fault a physician will have.

Frequently, too, the specialist does not recognize the difference between dislocation of the columnar cartilages and an ordinary enchondroma, but picks up his saw and removes all anterior excrescences alike, leaving a place which will always be annoying to the patient. Close discrimination and the knowledge of when to operate should be the aim of every physician, be he specialist or not.

In conclusion, I have but a few words to say. The greatest trouble with physicians in general is, I believe, the failure to study minutely the history and symptoms of every patient before prescribing or administering treatment. The failure to make a proper diagnosis is the cause of most of the failures in a physician's work, and a physician to be successful must be a close, practical, and discriminating student. Men who have large practices are so apt to become routine in their methods, instead of studying each individual case, that they are often unsuccessful when just the opposite could be the case. Not long since I saw a case of paresis of the left vocal cord in a man who had been treated for three months for chronic laryngitis. His chief symptoms were hoarseness and fatigue after the use of the voice. Now this man had a difficult larynx to examine, but after repeated trials I was enabled to find the real cause of the symptoms. The physician who had been treating him recognized the hoarseness, and as it was chronic in character he simply made a snap diagnosis and so treated the patient without taking the tedious trouble to overcome a laryngeal spasm and obtain a clear laryngeal picture. Hence, I say there are two fallacies in medicine: first, that which is the result of ignorance from the lack of previous training and study; second, that which comes from making a snap diagnosis without minutely studying the case. Both classes are guilty, and in the long run the beneficent public will find out the physician upon whom they may depend.

THE IMPORTANCE OF A KNOWLEDGE OF THE PHYLOGENETIC DEVELOPMENT OF THE CHILD IN THE PREVENTION OF CHILDREN'S DISEASES.[1]

By E. STUVER, M.D.,
of Fort Collins, Col.

In this age of world encircling intellectual activity, in which mind has penetrated so many of the secrets of Nature, and by directing its forces has secured such a great dominion over matter; when the thought and discoveries of the whole world are at the command of each individual worker we are prone to lose sight of the fact that while mind controls and directs matter, matter, on the other hand, exerts a powerful influence on the normal development and integrity of mind. Surrounded as we are by free schools, almost universal educational facilities and a public sentiment which, subordinating nearly everything else to the cultivation of the intellect, rushes the child, scarcely out of the cradle, into the kindergarten and thence through various grades of schools, colleges, and universities until he or she emerges at the age of twenty-five or thirty years a finished product of our modern educational system, we are apt to forget that cultivation of the intellect or cramming the mind does not comprise the whole of the development, and indeed, that unless very carefully guarded, by overlooking or ignoring the proper training and development of the body as well as the laws governing the development of the mind in the race such training may do infinitely more harm than good.

The child, instead of being a "little man" with the same thoughts, feelings, inclinations, capacities and powers, only on a smaller scale than a man, is, in truth, an altogether different being, and may be aptly characterized in his various stages of develop-

[1] Read before the Colorado State Medical Society at Denver, Col., June 20, 1899.

ment as an epitome of the development of the race. He passes through the successive stages of savagery, barbarism, and semi-civilization before attaining to the full civilization in which we live. During this progress the spectral forms of his dead ancestors surround him on all sides, and the mighty mental accumulations and beliefs of a long forgotten past impress upon him the various stages of credulity, inquiry, faith and full blown reason through which these ancestors have passed. With these facts fully impressed upon the mind, and thoroughly grasping the great truth that a symmetrical development of all the powers,—physical, intellectual, and moral,—is necessary to the greatest happiness and welfare of the human being, let us see whether our habits of living and educational methods accord with these fundamental laws of development, and if not, in what way the physician can help to point out the remedy.

As before indicated, the child is not a "little man" In both organization and function there are great differences between the two, and hence their nature and training should be different and made to conform to their organic and functional capacities. The glands, heart, lungs, muscular and osseous systems of the child possess a high degree of organic and functional perfection, and this would logically seem to indicate that the proper exercise and development of these various organs and systems is the rational and proper occupation of the child during childhood and early youth. In support of this inference it may be said that in the savage and barbarous stages of development of the race to which the young child corresponds these organs and functions are developed to a high degree of perfection. Such things as weak flabby muscles, flat chests, failing hearts, and impaired digestive organs were unknown, because their existence would have meant extinction to their possessors.

The muscular, osseous, and respiratory systems were developed to a high degree of perfection which was attained, not by disuse and confinement in ill-ventilated rooms for a considerable part of the day and the whole of the night, but by a careful and systematic exercise of the organs undergoing development. But while the physical organization was systematically developed and attained a high degree of perfection, and the special senses, especially the sight and hearing, were carefully trained from the earliest childhood until they became phenomenally acute among savage races, the intellectual development in many particulars remained in a rudimentary state. The powers of continuous mental application, abstract reasoning, and broad generalization were unknown to the savage, and were only acquired by the race through the slow, gradual process of evolution.

In support of the proposition that the young child represents and epitomizes the far away savage stage of the race from which he sprung, we have the further fact that while the organic development and functional capacity of his heart, lungs, glandular organs and muscular and osseous systems have reached a high degree of perfection at birth, on the other hand his nervous system is in a very immature and undeveloped state. The brain of the young child, as compared with that of the adult, contains a larger percentage of water, is softer, more easily irritated, and is much sooner fatigued on mental exertion; but, on the contrary, the perceptive faculties whose development depends on the training of the special senses are keen and alert and attain a high degree of perfection if given an opportunity in childhood to develop in accordance with the laws impressed by Nature upon the race throughout the ages.

With these principles clearly in mind let us see what application can be made of them by the physician in warding off physical and mental ills, and helping the individual and the race to attain the highest physical, intellectual and moral perfection and happiness. When we consider the phylogenetic history which the child represents at the time of its birth, the æons of time, and the enormous evolutionary progress through which it has already passed we can have some appreciation of the force and wisdom of a remark once made by Dr. Oliver Wendell Holmes, that in order to treat the child successfully, one ought to begin two hundred years before it is born. So strong are hereditary tendencies that no matter how favorable the environment may be they influence either for weal or woe the individual and his offspring for generations. This brings us to the first fundamental proposition, *viz.*, that in order to reach the highest development and the most complete living the individual should be well born; that is, both parents at the time of procreation should be in good health and free from all taint of tuberculosis, syphilis, carcinoma, or other hereditary or communicable disease or constitutional predisposition to the same. Then during pregnancy the mother should obey the laws underlying good hygiene and correct living in the matters of proper clothing, diet, exercise, and the avoidance of all stimulants and narcotics, as well as late hours and undue emotional excitement which has a peculiarly pernicious influence upon the rapidly developing fetus. One night of dissipation may cast a shadow over a thousand years of the phylogenetic history of the rapidly developing embryo. After

birth the infant should be nourished at the maternal fount designed by Nature for its sustenance, and if the mother has been properly cared for during pregnancy she will in almost every instance have an abundance of milk, and it will be a rare thing indeed to be obliged to feed the child on cow's milk, or the many nostrum foods with which the market is flooded. Then, too, it should be zealously guarded against poisoning by stimulants and narcotics in any form. Opium and alcohol in all their varied forms, with their siren and delusive promises should be forever banished from the nursery and the child at least be given an opportunity to select its own drug habits in later years without having them forced upon it at this early age.

Right here I want to make one suggestion: as you all very well know, water is the great solvent on which the system depends to convey nutritive material to every cell and tissue of the body, as well as to remove their accumulated waste and broken-down products. These cells and tissues are surrounded by dialyzing membranes through which a constant endosmosis of nutrient material and an exosmosis of retrograde products is going on. An abundance of water is necessary at all ages to keep these membranes in good working order, but especially is this true in infancy and childhood when the assimilative and eliminative functions are so active. Often young infants cry from so called colic, and are dosed with brandy, paregoric, or some such abomination, when they are suffering from thirst, and a few spoonfuls of cold water will relieve the difficulty and they will fall into a peaceful sleep. All young children should have plenty of pure water at regular intervals.

The clothing should be made so as to give free movement to the limbs and permit a natural and unrestrained development of all the organs and functions of the body. The young child should have at regular periods an abundance of plain, non-stimulating food and plenty of exercise and spontaneous play in the fresh air and should at an early age be trained to habits of regularity in attending to the functions of the body. As childhood is the time of active development, and as sleep is Nature's great upbuilder and restorer children should have an abundance of sleep during all these years and especially while attending school.

All stimulants and excitements, such as late hours, children's parties, and the many artificialities of our so-called advanced civilization which tend to bring about a premature maturity should be strictly avoided. During childhood, when their perceptive faculties, memory, and imagination are active, children should be brought in close contact with Nature from which they will gain far more physical strength, mental power, and wisdom than can be obtained from the formal methods and conventionalities of most of our schools. And right here I desire to enter a protest against the long hours, continuous mental strain, cramming methods, and forcing processes of most of our modern schools. Scarcely is the child out of the cradle before it is sent to a kindergarten school; here if it is so fortunate as to have a teacher who understands and is thoroughly imbued with the true spirit of Froebel's teaching, it passes a happy time, and receives much benefit. Its books are plants, flowers, trees, fruits, birds, insects, and the various objects, animate and inanimate, of the external world by which it is surrounded. The everlasting hills, rising in majesty and grandeur, the soughing of the wind among the trees, the murmur of the brooks, the glorious sunsets, the autumn forest with all its gorgeous hues and kaleidoscopic changes,—in short, the almost infinite variety of objects and the innumerable beauties of Nature can be made most impressive sermons by the true kindergarten teacher,—sermons which will sink deep down into the soul of the child and leave an impression on its body, its mind, and its character which the storms and vicissitudes of life will never obliterate. But, alas! such teachers as we have in mind are like angel's visits—rare, indeed—and come to us like a ray of hope from the great beyond. In the majority of instances even the life of the kindergarten is smothered by the blighting curse of formalism, and instead of being a blessing it is made a curse, and through ignorance or disregard of the most rudimentary physiologic laws lays the foundations of physical defect or disease.

But if this is true of the kindergarten, what shall be said of the average primary school? In the words of Dante, there should be inscribed over the portal "He who enters here leaves hope behind," because from my observation and information about our schools, from the time the pupil enters the first primary grade until he completes the grammar-school course he is continually subjected to such a grind and cramming for examinations that he must indeed be made of stern stuff if he does not emerge from this course weakened both in body and mind. The object of all true education should be a well rounded, symmetrical development of all the powers,—physical, intellectual, and moral—of the individual; but in the face of this truth which is acknowledged by all educators worthy of the name we see children from six to fifteen years of age during the time of intense developmental activity subjected to a course of study which, in many instances, is entirely beyond their comprehension, and a source of

constant irritation to their immature and unstable brains. Especially to be deprecated is the everlasting number work and arithmetic drill which appears to have become a mania with the greater number of the teachers in our schools to-day. From the time the unfortunate child enters the first primary, through the eight long years until he emerges from the grammar course, he is subjected to a continual grind in number work, problems, and examinations. Morning, noon, and night these are a veritable "Old Man of the Sea" to them, hanging like a pall over their hours of leisure and even invading their dreams; they become not only a menace to the health and happiness of the children, but also a nuisance to their parents who cannot enjoy a quiet half-hour because a puzzled child cannot solve a long list of problems far beyond its comprehension, and appeals for help.

But, after all, what results are attained from all this work, worry, and grind? I believe I am justified in saying that they are nearly always inadequate, and often a dismal failure, and that any eleven- or twelve-year old pupil who had never looked into a written arithmetic, but who had been carefully drilled in mental arithmetic, can do better work and obtain a clearer comprehension and more thorough grasp of the subject in three or four years than the struggling child obtains by its eight years of arduous and detestable toil. Then, too, the system of examinations in vogue in so many schools is a veritable *bete noir* to the pupils who are kept in a constant state of worry and irritation and subjected to a continual nervous strain. The work, instead of being inspired and vitalized by a love for truth and a desire to penetrate and understand the secrets and laws of Nature, becomes a mere mechanical cram and filling-up process to pass the examinations. This sort of work, as every one knows, has not only little real educative value, but by leading to makeshifts and subterfuges of various kinds as well as downright cheating degrades the pupil. Healthy mental and physical growth and activity are conditioned on an enjoyment or appreciation of the work being done. A distasteful task or one done under compulsion fatigues the mind much sooner and leaves a much more evanescent impression than one which arouses the pupil's enthusiasm and engrosses his whole attention.

When the teacher so directs the pupil as to call his physical and mental powers into play simultaneously the dry rot of formalism and routine vanishes as if by magic from the school, and instead of the tired disgusted look on so many young faces produced by the mechanical leveling process, which by confining within restricted bounds reduces all to the same plane of mediocrity, we see the flashing eye, the eager intent purpose, and the whole soul of the pupil aroused by a noble enthusiasm. Who will say that in true educative value one hour of such work is not worth weeks, nay months, of spiritless cramming?

Nor are spontaneity and interest less important in physical than in mental work. Free, unrestrained, spontaneous play in the open air is of infinitely greater value in developing the body than any indoor formal exercise, although properly directed gymnastic exercises, if subordinated to outdoor sports, can be made valuable adjuncts. So many pitfalls and dangers lie hidden in the pathway of the rapidly evolving child that in order to guide him wisely and safely through the intricate labyrinth, to avoid the Scylla of physical ills on the one side, and the Charybdis of mental evils and abnormalities on the other, it is necessary that the physician should at least have a clear outline knowledge of his evolution and know something of the physical and mental characteristics and potentialities impressed upon him throughout the ages.

MEDICAL PROGRESS.

Separation of the Symphysis Pubis During Labor.—Rutherford (*Louisville Jour. of Surg. & Med.*, June, 1899) reports the occurrence of the above rare accident in a woman aged twenty-eight years. She had had three previous labors, in two of which the child was delivered by forceps, while in the third craniotomy was necessary. In the fourth such strong traction was made upon the forceps that the physician felt something break. The forceps were removed, the uterus was kneaded, and the child was born spontaneously. Examination of the mother showed that the pubic bones had been separated at the symphysis. Recovery was tedious and complicated by septicemia, but was finally complete.

Apex Dulness without Pulmonary Tuberculosis.—Kernig (*Centralbl. f. Inn. Med.*, June 10, 1899) has found dulness in the apices of both lungs in patients who have been in bed for a long time with a wasting disease although no local pathological pulmonary condition was present. This fact was confirmed by autopsy in a number of cases. An observer might easily suppose that incipient or healed lesions of phthisis were present. The dulness is explained by the fact that the long stay in bed diminishes the amount of air in the apices so that the upper limit of the lung sinks and may even be retracted below the clavicle.

Operation for Congenital Phimosis.—Pousson (*La Semaine Medicale*, June 28, 1899) insists upon the desirability of obtaining primary union after operations for phimosis, as cicatricial bands and adhesions, especially in

the neighborhood of the frenum, will give trouble. His own operation is performed as follows: After disinfection an elastic catheter is wrapped twice around the penis back of the glans in order to control hemorrhage. A sound is introduced under the prepuce to break up any adhesions. The prepuce is seized with two clamps, one applied dorsally and one ventrally, and drawn forward. A fenestrated clamp is then applied transversely to the whole prepuce and back of it from eight to twelve threads of silkworm gut are passed through the flattened prepuce from side to side. The distal portion of the prepuce is then cut off and the sutures for the whole wound being in place are cut and tied. An extra stitch or two will be necessary at the frenum. The elastic catheter is removed and hemorrhage stopped by a hot antiseptic solution. An iodoform salve is smeared over the suture line. The stitches are removed on the fourth or sixth day. The results of this operation have been eminently satisfactory.

Anchylosis of the Jaw Due to Interstitial Myositis.—Seggel (*Duetsch. Zeit. f. Chir.*, May, 1899) describes a case of anchylosis of the jaw of rather unusual character. The patient was a woman aged forty-eight years who lost all of the molar teeth on the left side on account of caries. They were pulled out in a rough manner and marked inflammation followed each extraction. Three years after their removal the patient was exposed to a severe wetting and was thoroughly chilled. The left side of the face swelled badly and this swelling and pain lasted for more than three months. From that time on the cheek never regained its normal size but grew gradually larger without pain until it was impossible to open the jaw. A diagnosis of sarcoma of the ascending portion of the jaw was made and an extensive resection of the bone and soft parts, including the whole of the parotid gland, was carried out. Complete facial paralysis of that side resulted. The wound healed well and in six weeks the patient could open her mouth nearly an inch. The tendency of the jaw to fall to the right side was counteracted by a plate with an inclined surface. Microscopical examination of the excised muscle showed that its fibers were separated by a large amount of cicatricial tissue and the fibers themselves were atrophied. The question of syphilis, after careful consideration, was rejected. The lesions appeared to be due to traumatism at the time of the extraction of the teeth and to the inflammation caused at that time and after the exposure to the weather. Several similar cases have been reported, although usually anchylosis of the jaw is due to syphilis or to myositis ossificans progressiva or rheumatism.

Partial Retention of Urine.—Warden (*Edin. Med. Jour.*, July, 1899) says that the recognition of the condition of a bladder incompletely emptied by the urinary act is all important, although by no means easy. More than seventy-five per cent. of all cases of retention are due to prostatic enlargement. Complete retention is the late phase of the condition in these patients, while incomplete retention is very gradually established and often not recognized for years. The early symptoms therefore should be carefully watched for. These are nocturnal polyuria and persistent digestive troubles. Everything which favors local congestion, such as prolonged lying in bed, too sedentary a life, too rich a diet, a surface chill, disregard of Nature's call to urinate, sexual indulgence, tends to bring on an attack of retention. The bladder should be evacuated slowly and if there be any pain during the process, it will be well not to draw the urine completely off but to inject small quantities of warm boracic solution until it comes out as clear as when it was injected. In this manner the urine may be entirely withdrawn without emptying the bladder. If it is difficult to pass a catheter every two, four, six, eight, or twelve hours, as may be needed, it should be tied in, for artificial evacuation may be required for days. The golden rule is to empty the bladder often and aseptically for a considerable length of time. If the early period of prostatic enlargement be tided over successfully, one may be spared the greater anxiety of later complications. As the stagnation becomes more chronic, the complications and alterations in the general health rather than in the local condition make themselves felt. The bladder may consequently escape examination for months, although in all obstinate gastric derangements it is well to suspect and search for some intoxicating agent. When stagnation becomes so extreme as to be accompanied by obstinate distention of the bladder, it forms the most serious, most intractable, and yet the most overlooked of all varieties of partial retention of urine. The distention extends throughout the whole urinary tract from the bladder to the kidneys and, although in the beginning there may be no infection, the fundamental disorders will soon become organic. The patient's tongue is red and dry so that swallowing is intensely distasteful. There may be vomiting and diarrhea or constipation of an obstinate form. The pain, loss of flesh and appetite, together with the cachectic appearance and age of the patient, often suggest to the physician the diagnosis of cancer of the stomach. Inquiry will show that these patients are passing large quantities of urine, generally about one hundred ounces in the twenty-four hours. The urine is usually pale and clear. It cannot be too dogmatically stated that when these three symptoms—polyuria, frequency of micturition, and grave digestive troubles—are present the cause is almost sure to be a bladder which the patient cannot completely empty. Evacuation of the bladder should be begun slowly and very cautiously and may be increased to three or four times in the twenty-four hours if all goes well. The catheterization should be of such frequency that the patient is conscious of no strong desire to micturate, and upon each occasion a small quantity of solution should be left in the bladder. If infection is present, the bladder should be washed out with boracic solution or silver nitrate, $\frac{1}{1000}$. Along with local treatment the diet should be a generous one. Much milk, beef-juice, custards, eggs, etc., and bitter vegetable tonics and saline laxatives should be administered. Healthy out-of-door exercise in moderation is also recommended. If these principles of treatment are intelligently followed, excision of the prostate and castration can be reserved for intractable cases.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 19, 1899.

THE BRITISH MEDICAL ASSOCIATION MEETING.

British and American medicine have been drawing closer and closer together for many years. The meeting of the British Medical Association in Canada two years ago gave progressive American physicians a living interest in the annual meetings of that body. The general course of events since that time has served to bring the two nations closer together in all their interests and community of language in the midst of strife has proved a bond of union more vital, though unsuspected, than would have been credited before the event.

We feel, then, in devoting considerable space this week to the proceedings of the annual meeting of the British Medical Association, which was held this year from August 1st to 4th at Portsmouth, England, that we are but responding to the wishes, expressed and unexpressed, of many of our readers who are anxious to know the latest views of the English-speaking branch of the profession across the water. The interest of the meeting is well reflected in the abstracts from the official addresses which we publish, and which serve well to show the trend of English medical opinion.

The conclusion of the President's address, in which he dares to prophesy a death-rate of 10 to 12 per 1000 for the population of our great cities before the new century is very old, is especially interesting. He does not ground his hopes on any new system of sanitation or tenement-house reform, but on the more intelligent and complete application of present methods. What is needed much more now than elaborated systems of improvement in the dwellings of the poor in cities is the intelligent cooperation of the inhabitants of the poorer quarters of our cities in the schemes for the amelioration of their sanitary condition. No amount of reform would be permanently successful without this. It will not require much teaching, but somehow an effectual recognition of how much they are able to make life more pleasant and more livable for themselves and families in the enjoyment of health, by the observation of simple sanitary measures, must be brought home to all the population.

The Address in Surgery contains a plain statement of certain facts with regard to the status of medical officers in the British Army that may well serve as an excellent lesson for our Government. We have entered upon a phase of our development as a nation which seems inevitably about to require a larger number of soldiers on the active list than before. It will be well to learn by British experience rather than our own the danger of neglecting the medical corps of the army. The necessity for keeping the medical corps at the highest possible condition of efficiency is well stated by Professor Ogston and the corollaries of that proposition, that army medical positions must carry with them the honor, rank, and emolument necessary to attract and retain the very best intellectual material from among the young medical men, are well and effectively brought out.

The Address on Tropical Medicine is one of the most interesting and complete of the series. England has taken up the white man's burden and English physicians at home are realizing their share of it and that on them and their work must depend the discoveries that will lift from the tropics the awful pall of indigenous disease which now makes them the tomb of so many Europeans. There is a lesson here, too, that we Americans may well take to

heart. We are entering on a period when many of our own citizens will deem it advisable to take up a tropical residence. Considering the proximity of our southern shores to tropical countries we have not as yet done the work in tropical diseases that might be expected of us. Especially the opportunities provided by our great ports of entry have not been used to as much advantage as they should as regards the opportunities they afford for the study of tropical diseases. Here is one of the great openings for American medicine in the new century.

CEREBROSPINAL MENINGITIS AND ANTERIOR POLIOMYELITIS.

We called attention to the fact not long ago that a series of epidemics of cerebrospinal meningitis were being reported from various parts of the country. We took occasion to point out about the same time the very practical medical importance of the careful study of all circumstances connected with cases of the disease and the benefit that might be anticipated from detailed reports of various epidemics. Our suggestion was accepted in certain quarters and we have had the opportunity to present to our readers accounts of a series of epidemics of the disease.

One thing is clear beyond a doubt, that this year in a number of different parts of the country, there has been an incidence of the disease quite unusual in its frequency and virulence. The conservative opinions of old practitioners would seem to indicate, however, that they are not surprised to meet with cases of the disease occasionally in their practice and that the disease must be considered in a way as endemic among our poorer population, at least in the larger American cities. The interesting question, then, is, How does the disease-germ maintain its existence in the interval between epidemics? Does it perhaps masquerade in the meantime under the guise of some milder or at least quite different form of disease and so escape recognition?

We have pointed out that at least one very conservative clinician in Europe has demonstrated the presence of the meningococcus intracellularis which is now generally accepted as the specific germ of cerebrospinal meningitis in the cerebrospinal fluid obtained by lumbar puncture from recent cases of acute anterior poliomyelitis. It is interesting to note, then, that following the report of a number of epidemics of cerebrospinal meningitis throughout the country, there should come accounts of an unusual incidence of anterior poliomyelitis in children this season. The daily newspaper press has had reports of a number of cases of this disease occurring, as has been noted not infrequently before, almost as an epidemic in some places. In the larger cities, as here in New York and in Chicago, we understand there is an impression that more cases of the disease are seen in private practice than usual.

Of course this does not connect the two diseases with any assurance, but it makes the study of their relations doubly interesting. Smallpox and chickenpox are usually considered as very far apart yet the Vienna School of Dermatology has not given up teaching that they are due to the same virus modified by conditions. Professor Senator of Berlin, a most conservative observer, says that whenever an epidemic of chickenpox occurs among the patients who come for treatment to his Polyclinic he expects to hear within the next few days of smallpox cases somewhere in the city and is seldom disappointed in his expectations.

Whether cerebrospinal meningitis and acute anterior poliomyelitis hold some such relation as this to one another will make an interesting question for study. We shall be glad to receive accounts of epidemics or sporadic cases of acute anterior poliomyelitis in which some connection with cerebrospinal meningitis seems possible, or in which symptomatic or other conditions seem to connect them.

The discussion of the question must serve to throw additional light on two very important diseases of children, in which the need for more light is only too evident.

ECHOES AND NEWS

Legacy for the University of Bonn.—Herr O. Holterhoff, a banker of Hannet, a small town in the German Rhineland, has bequeathed his property, estimated to be worth 1,000,000 marks (about $240,000), to the German University of Bonn.

Professor Roentgen Called to Munich. — Professor Röntgen of X-ray fame has received a call to the Chair of Physical Science at the University of Munich, Bavaria. He at present holds the same professorship at Würzburg, and recently refused a call to a chair at Leipsic. It is not thought that he will leave Wurzburg to accept the present call.

A New Feature in Bacteriology.—One of our non-medical contemporaries is responsible for the following: Mrs. Malaprop's country visitor had a sore back and her kind hostess insisted on her seeing a distinguished bacteriologist because, as she said, she had heard so much about recent advances in backteriology that she felt sure he would do her friend good.

Dangers of Medical Practice in East London.—It has always been understood that a doctor is safe from attack by nocturnal marauders, but the experience of certain physicians in East London recently proved that either this immunity never existed or that it no longer passes current. In consequence some of the physicians go about armed after dark while a greater number refuse to leave their offices unless adequately protected.

Medicine and Religion.—The Russian authorities limit the number of Jewish physicians to five per cent. of the total number of physicians engaged in practice. This is not a law of the government but merely an act of the examining board. As, however, no one can practice without a license from this board, it is easily seen that the board has no difficulty in enforcing its act, by refusing to grant licenses to Jewish physicians in excess of the stipulated number.

Russian Students Pardoned. — The Russian Minister of Public Instruction has issued a proclamation by order of the Czar to the effect that all students who took part in the University student disturbances last year are pardoned excepting only those who for special offenses or reasons are entirely excluded from attendance at the superior schools. Most of the students return to work toward the end of this month, some, however, not until August, 1900.

An Expensive Criminal Family.—Ada Zurke, who was born in Germany in 1740 and died in 1800, was a confirmed drunkard. Professor Pelimann, of the University of Bonn, discovered and identified 709 of her descendents. Seven of these were convicted of assassination and 76 others of different crimes, while 144 were professional beggars, 61 lived on public charity, and 181 were prostitutes. Altogether, the cost to the German government of watching, pursuing, trying, and boarding the members of this family, has been more than a million and a quarter of dollars.

Prizes for Work on Malaria. — The Committee of the Société des Etudes Coloniales of Brussels, Belgium has offered two prizes for successful investigations in malaria, each of the value of 2500 francs—$500. The first is to be awarded to any one who shall considerably advance our knowledge of Laveran's hematozoon malariæ in its cycle of existence, either within or outside of the human body. The second is to be conferred on any one who shall determine the exact etiology of the so-called malarial hemoglobinuria, the *fievre biliare hæmoglobinurique* of the French.

Koplik, or Flindt or Flindt-Koplik?—It now appears, according to a writer in the *Weiner Medicinische Wochenschrift*, that the early mucous eruption occurring in measles, the lesions of which have now become generally known as "Koplik spots," was described by a Danish physician named Flindt in 1880. The description corresponds so closely to that given by Koplik that there is absolutely no doubt that the eruption is the same. Will these spots be known to posterity as Koplik spots or Flindt spots or Flindt-Koplik spots; or will they again be forgotten and rediscovered, by some other observer?

Vicious Tubercular Patients.—An Italian correspondent of *Temps* mentions some murderous attacks upon nurses and doctors by tubercular patients in the hospital Santo Spirito. In one instance, in which a Sister of Charity was assassinated, public opinion inclined to the view that the patient was justly enraged on account of inhuman treatment; but in another instance a man who desired to be admitted, killed the examining physician because he was refused, so that the treatment in the hospital does not wholly explain these outbreaks of anger, which are the more remarkable as occurring in patients whose resignation and optimism are proverbial.

Professor Pflueger's Seventieth Birthday.—Professor E. Pflüger celebrated his seventieth birthday toward the end of July. He is the well-known Professor of Pathology at the University of Bonn in the German Rhineland and the editor of the widely read *Archiv für Physiologie* which is usually known as "Pflüger's Archiv." He is still hale and hearty and is doing excellent original work and directing others in his laboratory at the University. He is not, however, a great exception in this respect among distinguished professors at German universities since there are quite a number of septuagenarians still in active work and some few of more than three score and fifteen who have not as yet put off the professorial harness.

Professor Sanarelli's Reported Visit to America.—A recent number of *Science* published the announcement of a prospective visit of Professor Sanarelli of Bologna, Italy, to this country, in order to study the effects of his serum in the treatment of yellow fever. Other American journals have also published the item. As we have been in communication with Professor Sanarelli very recently we think we are in a position to correct this statement. Toward the end of July he wrote from Bologna that he was about to leave the city for a three- or four-months' vacation and that his address in the meantime would be Pratovecchio Arezzo. This for those who may care to communicate with him during the next few months on any of the important questions connected with his yellow-fever discoveries. Professor Sanarelli is very much interested in American medicine, and as his article in the MEDICAL NEWS last week showed, has been following our medical literature very carefully, but he has no present intention of paying us a visit.

Tropical Researches in Malaria.—The expedition sent

out by the Liverpool School of Tropical Diseases under the command of Surgeon-Major Ross for the investigation of malaria in South Africa sailed on July 29th. The English Colonial Office took the greatest interest in the matter and offered to help by every means in its power. The authorities at Sierra Leone have been instructed to furnish ever facility for the successful carrying out of the work of the expedition. Among other things the British Museum directors were asked to send their dipterologist, Mr. E. E. Austin, with the expedition, the Colonial Office offering to pay his expenses. The definite discovery of the exact species of mosquito that carries the plasmodium malariæ is considered of primary importance for the questions of prophylaxis and eradication of the disease that are now so prominently matters of consideration. The Belgian Government, interested in the matter because of its possessions on the Congo, has sent an officially nominated delegate, Dr. S. Van Neck, to visit and report on the Liverpool School of Tropical Diseases and to accompany the expedition.

Belgian Work in Tropical Diseases.—The sum of 50,000 francs ($10,000) was recently contributed to the colonial department of the Belgian government for the purpose of furthering investigation in "colonial pathology." A committee of the Société d'Etudes Coloniales at Brussels was appointed to consider the best manner of making use of the gift, the generous donor of which wishes to remain anonymous. It was finally decided to employ the fund thus created for the equipment and support of a scientific expedition to be sent to the Belgian possessions on the Congo in South Africa, for the purpose of studying the diseases of tropical climates in that region. Dr. Van Campenhout, a medical officer of the Belgian army, who had been twice on duty in the Congo region before, was selected as the head of the expedition and with him was associated Dr. Redding. After a great deal of preparation they set out at the beginning of last month. The Belgian government in South Africa (the Congo State) has established at Leopoldsville a well-equipped physiological and bacteriological laboratory in which the work of the expedition is to be carried out. We have noted above that a medical representative of the Belgian government accompanied the English medical expedition to Sierra Leone which set out only a month later, so that the deep interest in Belgium in tropical diseases and in making the Congo region more habitable for Europeans is evident.

Next Annual Meeting of German Naturalists and Physicians.—This year's meeting of this association is announced for the week of September 17th to 23rd at Munich, Bavaria. German physicians have been complaining for some years of the yearly increase of the number of sections and the consequent division of the work so that a satisfactory glance at medical and scientific progress during the annual sessions is more and more impossible but so far their complaints have been to no purpose. This year there are to be no fewer than 37 sessions, 17 in the natural sciences, 20 in medicine. Two general sessions are held at each annual meeting. This year three addresses are to be given at each of them. At the first general session Dr. Fritzjof Nansen, the famous Polar explorer, will lecture on "The Results of My Expedition to the North Polar Region"; Professor Ernst Von Bergmann, Professor of Surgery at the University of Berlin, will talk on "Radiography in the Treatment of Surgical Diseases," and Professor Foster will lecture on "The Change in the Astronomical View of the World During a Century." At the second general session Professor Birch Hirshfield, Director of the Pathological Laboratory at the University of Leipsic, will deliver an address on "Science and Medicine"; Professor Boltzman will discuss "The Recent Development of the Methods of Theoretical Physics" and Professor George Klemperer of Berlin will lecture on "Justus Von Liebig and Medicine."

International Conference for the Prophylaxis of Syphilis and Venereal Diseases.—At the meetings of the conference to be held in Brussels, September 4, 1899, and the following days, besides the prophylaxis of venereal disease, the question of methods for the control and regulation of prostitution is to be discussed. Papers are to be read by Drs. Fournier of Paris, Neisser of Breslau, Lassar of Berlin, Finger of Vienna, and by a number of others prominent as students of these questions. The committee has appointed the following physicians as delegates to investigate the conditions of prostitution in their respective countries: Argentine Republic, Dr. Baldomero-Sommer, Buenos Ayres; Austria, Dr. Finger, Vienna; Drs. Bayet and J. Verhoogen, Brussels; Bosnia, Dr. Gluck, Savajevo; Chili, Dr. Valdes-Morel, Santiago; Denmark, Dr. Ehlers, Copenhagen; England, Dr. Geo. Ogilvie and Dr. Drysdale, London; France, Drs. Ozenne and Julien, Paris; Germany, Drs. Blaschko, Berlin, and Neisser, Breslau; Hungary, Dr. Rona, Budapest; Holland, Dr. Selhorst, The Hague; Italy, Dr. Tommasoli, Palermo, and Dr. Bertavelli, Milan; Norway, Dr. Axel-Holst, Christiania; Roumania, Dr. Petrini de Galatz, Bucharest; Russia, Dr. Petersen, St. Petersburg; Sweden, Dr. Welander, Stockholm; Switzerland, Drs. Jodassohn and Schmidt, Berne; Turkey, Drs. Von Duhring and Zotos, Constantinople; United States, Dr. Isadore Dyer, New Orleans. Dr. Dyer, the delegate from the United States asks that any data bearing on the subjects to be discussed at the conference be sent either to Dr. Dubois Havenith, Secretary-General of the Conference (15 Rue du Gouvernment Provisoire, Brussels, Belgium) or to himself (at 124 Baronne street, New Orleans, La.). Dr. Dyer has already sent to the health boards of all cities in the United States containing more than 20,000 inhabitants a list of questions the answers to which will supply useful information for the purposes of the conference, as to the state of affairs at present existing in this country in the matter of prostitution and venereal diseases. A copy of these questions, which are very pertinent and suggestive, will be sent on request to any one who is interested in the subjects to be discussed at the conference and who thinks he can supply useful and pertinent information.

MEDICAL MATTERS IN NEW YORK.

SMALLPOX ON A LINER—HORGAN AND SLATTERY, ARCHITECTS—MAN WITH TWO HEARTS—MANY STREET-CAR ACCIDENTS—VETERINARY COLLEGES UNITE—VIOLENT DEATH OF INSANE PATIENT—CHRISTIAN SCIENCE AND THE CORONER.

THE Red-Star Line steamship "Kensington" arrived on August 8th from Antwerp, having on board a boy twelve years old, a steerage passenger who had been stricken with smallpox on July 29th, and was immediately isolated in the ship's hospital. No other cases were found, but the ship was detained until the possible exposure of the passengers and crew could be determined.

We learn that Messrs. Horgan and Slattery, "the official architects" of this municipality, have filed plans for a new two-story building on the north side of Sixteenth street, east of Avenue C, to be used as an office building by the administrative staff of the Willard Parker Hospital. The building is to cost $16,000. Mr. Horgan, at the Mazet investigation a few days ago, announced himself to be "the equal of any architect living," and Mr. Slattery, when questioned concerning his qualifications, said that he "didn't know nothing about such things. You'll have to ask my partner." We may, then, expect a creation eclipsing the poems which Phidias shaped in stone. But we had better not be too sanguine, for Mr. Horgan's most brilliant successes have been in the construction of mud-scows.

There are members of the lay press who have about as much knowledge of anatomy as a Christian-Scientist has. It is related that "a man who has two hearts" called on a Brooklyn physician, Dr. John H. Lawrence of 347 Jay street, who examined both sides of his chest and found a heart on each side. Then the patient, "by some muscular contraction, pulled one of his hearts down into the lower lateral portion of his pelvic cavity, while he held the other heart in its normal position. Then he reversed the position of the two organs, and the physician in each case plainly felt the thumping of the organs as the blood was pumped through them." Or may we suspect that this newspaper man was indulging a sense of humor?

The report that the State Railroad Commissioners propose to take some action during the coming winter to prevent the numerous accidents caused by the various trolley lines throughout the State calls attention to the number of street-car fatalities recorded by the Health Board of this city. During the first quarter ending March 30, 1899, there were twenty-eight people killed by this city's elevated and surface roads. During the second quarter there were twenty two killed by these agencies.

It has been decided to consolidate with the New York University the New York College of Veterinary Surgeons, chartered in 1857, and the American Veterinary College, established in 1875, these being the only institutions for teaching veterinary science in this city. All the members of both faculties resigned, and a new faculty was appointed, principally from among their number, with Professor Alexander F. Liantard of the American Veterinary College as dean. Among the Faculty are Professors John A. Mandel and Edward K. Dunham, and Dr. William H. Park, all of the New York University and Bellevue Hospital Medical College. The consolidation was made in obedience to the principle now generally accepted in America that each degree-giving professional school should be part of a university. The new school will open its first term October 2d at the college building, 141 West Fifty-fourth street.

Coroner's Physician Hamilton Williams made an autopsy on the body of James McGuire, a paretic who died in the Manhattan State Hospital on Ward's Island on August 5th, the result of which led to the commitment of Keepers Sexton, Ryan, and O'Donnell in the Tombs pending the inquest. Keeper Whyte was sent to the House of Detention as a witness. Dr. Williams found scarcely a spot on the man's body free from contusions. Six ribs were broken. "The kidneys and liver had been badly bruised." There was a large egg-shaped bruise upon the back of the head. The intestines were torn and bruised, the peritoneum was torn almost to shreds and there were about three pints of blood in the abdominal cavity.

The New York State Lunacy Commission will consider the case of McGuire. It has received a report from First Assistant Physician Rowe of the Manhattan State Hospital, in which it is stated that as the patients were about to go out for exercise McGuire suddenly turned upon Attendant Ryan and struck him in the neck with his fist. "Two other attendants came to the assistance of the first and endeavored to control the patient, but being a powerful man, they were obliged to place him upon the floor, two bearing down upon his arms and chest, the third holding his feet. After his paroxysm he was allowed to get up and go into the wash-room. Returning to the ward he sat down, but the attendant, noticing he was very pale, sent for the ward physician, who administered stimulants, but the patient died in a few minutes." McGuire suffered from general paresis. He was of very powerful physique and boasted of his strength as a wrestler and as a "strong man." It is well known that the bones of the insane are more easily fractured than those of other people.

John A. Campbell, sixty-four years old, a teacher of the doctrine of Christian Science, died August 11th at his home, 118 East Ninety-second street. He had suffered a stroke of apoplexy several days before and was attended by two so-called Christian-Science "healers." The evening previous to his death Dr. J. S. Sobel of 1421 Lexington Avenue was called in, but the "healers" would not consent to his treating the patient. Dr. Sobel then notified the Board of Health. Detectives, on going to the house, were shown a death-certificate signed by Dr. Jennie E. Gore of 1145 Park Avenue, on which the cause of death was stated to be "cardiac paralysis induced by apoplexy." Dr. Gore had been called in at 11 A.M., four hours before the man's death. She said she had given a death-certificate in the belief that as another doctor had preceded her it was all right to do so. The law requires that the physician granting a certificate of death shall have been attending the patient for twenty-four hours prior to the person's death; otherwise the case

must be put into the hands of the coroner. Coroner's Physician Weston made an autopsy on the body of Campbell on August 12th. Cerebral hemorrhages and pleurisy were found. Coroner Fitzpatrick will make an investigation.

No reflection upon Dr. Gore is intended in the following extract from the report of the investigation concerning Christian Science made for the MEDICAL NEWS (*vide*, p. 170, January 21, 1899. "The following observation will tend to illustrate the inherent dishonesty of this movement: One of these 'healers' complained to me of the disadvantage at which Christian Science is placed in these times. Should one of their patients die the case must become a coroner's case and be subject to his investigation. A Christian-Scientist's certificate of death would not be accepted. Therefore, should they get into any trouble of this sort, they have to seek (and it is declared they sometimes find) an obliging physician who will get them out of their trouble by signing a certificate for them."

Coroner Fitzpatrick is an honest and a just man; and the combative temperament of the Celt is well developed in him. And if his political superiors will not interfere with his work we may expect from him a vigorous investigation of this case.

CORRESPONDENCE.

YELLOW FEVER AT HAMPTON, VA.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—The yellow-fever epidemic may safely be considered as under control, if not ended. There are no cases outside the Soldier's Home, to which place there will be no trouble in confining the disease. On the advice of the surgeons of the Marine Hospital Service (the officers of the State Board of Health approving) the Board of Health of this town decided on August 10th to raise its quarantine against Hampton, Norfolk, and Warwick County, the Soldier's Home and Phœbus, however, remaining strictly guarded with a double cordon. It looks now as if the quarantine against Phœbus will be raised to day, there having been no case there for fourteen days. As a matter of fact, it is the opinion of Dr. Wasdin that but one of the three cases reported at Phœbus was true yellow fever. The second so-called case was not seen until convalescence had begun and he preferred as a matter of precaution to look upon it as a case of yellow fever and treated the patient accordingly.

Norfolk raised its quarantine against this part of the world on August 12th, and so ends, I think, what threatened to be a most serious outbreak of this dread disease. This surprisingly rapid eradication is the result of the magnificent work of Dr. White and the officers of the Marine Hospital Service associated with him. Now that it is over, the wiseacres, though many of them fled like sheep at the first report, are giving it as their opinion that because the fever did not spread it could not have been yellow fever, but as Surgeon-General Wyman remarked, if the Marine Hospital Service prevents an epidemic from spreading the Government is blamed for putting the people to the manifold inconveniences of quarantine but these people are only too ready to pillory the Service if the disease is allowed to get beyond control. It is only fair to the people of this district, however, to say that as a rule they behaved with the utmost common sense, and have given the officers of the Marine Hospital Service every consideration and help. It is pleasant to record, amid the utter indifference of the country toward the Marine Hospital Service and its surgeons, that the citizens of Hampton are about to present Dr. White with a handsome chronometer in recognition of his services in this crisis.

The indifference toward the Marine Hospital Service, strange as it may seem, is shared in almost as great a degree by the medical profession as the laity. They have but little idea of the splendid efficiency of the service under Dr. Wyman, and of the intelligent devotion of the surgeons to their duties. In the present epidemic, for instance, scarcely an hour had passed before the patients had been segregated and the infected localities placed under guard. A house-to-house inspection was immediately begun, not only in Phœbus, but in Hampton, Newport News, and in the entire neutral zone, extending from Newport News some thirty miles up the railroad. The writer was ordered to inspect Warwick and part of York County and drove upward of one hundred and twenty miles through the small towns and county districts inspecting houses and running down reports. No one who has not been in a yellow-fever district can have any idea of the false reports which get abroad, of cases here and there, and the terror which is spread by such statements; and it is plain that one of the chief duties of the Marine Hospital Service is to run down such stories and investigate cases of reported sickness.

Speaking of the terror which the mere mention of yellow fever causes, it seems to me it would be a good idea for the Government to print a pamphlet that could be understood by the laity, for distribution among the people, which should show the efficient way in which the epidemics since 1879 have been controlled, and the low death-rate from the disease. They should be made to know that yellow fever does not necessarily mean black vomit, for unquestionably this is their impression.

Speaking generally, I do not suppose that any one will deny that there should be a national control of all matters quarantine. As matters stand to-day the local boards are prone to give much consideration to the purely commercial side of the matter. Norfolk, for instance, quarantined against Newport News without any good reason for doing so, and Newport News naturally retaliated, and this brought about great loss to both places and considerable private deprivation. I am afraid that it is a great temptation for local boards to use their power in such cases for the pecuniary good of their towns without consideration of the intrinsic necessity of such rigorous procedure. The Marine Hospital Service as a national institution should have the power of deciding the question of quarantine in all instances.

FRANK DONALDSON, M.D.

NEWPORT NEWS, VA., August 15, 1899.

OUR FOREIGN LETTER.

[From Our Special Correspondent.]

THE SIXTY-SEVENTH ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION AT PORTSMOUTH.

PORTSMOUTH, ENG., August 2, 1899.

THE opening sessions of the sixty-seventh annual meeting of the British Medical Association at Portsmouth yesterday were only fairly well attended, the unusually hot weather working upon the British horror of being warm to keep many at home. The natives of The Island do not consider themselves healthy except when just on the verge of goose-flesh, save as a result of exercise and shiver themselves into rheumatism and bronchitis through the entire winter in their unwarmed houses, sustained by the sense of living up to their ideals of hygienic duty. The one thing they dread is being comfortably warm, which is "dangerous" according to their Puritanic health-creed, probably just because it is enjoyable.

Of course the actual business of the meeting does not begin until to-day and the tide of attendance was setting in strong last night and this morning but I fear the 1800 visitors anticipated by the local committee will hardly materialize unless a Polar change in the weather comes to-day, of which there could hardly be less prospect than at present. Another thing that makes the Englishman dread hot weather in town is his abject slavery in the matter of dress. The black coat and the silk hat are as *de rigeur* in any public place, except at a cricket-match or a race meeting, as the breech-clout in Timbuctoo, or rather more so, indeed. Few self-respecting Britishers would dare to appear without either, and ye English medical man is nothing if not proper, wearing his dress suit on every possible occasion, even to meetings of local medical societies.

It always strikes an American pagan curiously that the first morning of a medical association should be devoted to solemn religious opening services, in cathedrals wherever possible, with the added horrors of a long sermon by a solemn ecclesiastic, who probably for the first time in his life has a chance to tell a group of "*tres medici duo athieste*," as the old medical proverb ran, what he thinks of them from his pulpit without fear of reply. The usual burden of his song is how honored the profession ought to feel by the wonderful opening that it has for promoting the true, highest, *spiritual* welfare of humanity, by upholding the hands of God's only chosen professional servant—himself! Strange that our profession does not seem more sensible of the honor.

The chief subjects before the General Session in the afternoon were the Commissions' evil, the Midwife's bill, and direct representation of practitioners in the Medical Council. This last, under the leadership of that experienced warrior against ancient abuses, Mr. Victor Horsley, to whom the profession is already indebted for so many reforms, stirred up quite a hornet's nest, but progress was made, though after the native fashion, with much grumbling. Upon the Secret Commissions' question the council reported that they had heard allegations as to the acceptance of commissions by medical men from druggists, instrument-makers, and *even undertakers* [laughter] but upon investigating these rumors they had come to the comfortable conclusion that most of them were unfounded. Such as had any basis in fact referred to presents after and not to offers before, especially we trust in the case of undertakers. The failure of the Council bill for the registration of midwives was brought up by Dr. George Brown and the alleged bill for this purpose, now before Parliament, drawn up by the midwives themselves, was denounced as "the worst that could be imagined," which the Association endorsed by passing a strong resolution condemning it.

The Parliamentary Committee was thanked for its successful exertions on behalf of Dr. Lamont, the shamefully imprisoned vaccination officer of South Uist and a vote of condolence with the gentleman himself passed.

Dr. Ward Cousins delivered his President's Address in the evening, an interesting and most practical one. He could not, of course, resist the temptation of the classic *piece de resistance* on such occasions, a sketch of the progress of medicine during the present century, but this though so deadly familiar was well done and he soon got cleverly away from it. The "growing influence of the new methods of reseach" and "the decline of abstract reasoning and theoretical speculation" was rightly commended but not without a shrewd hint that it *might* be possible to keep our thumbs so busy that our brains have no time to work out their results, and that the highest function of the medical investigator is *not* to turn himself into a mere Babbage calculator, for registering mathematical results and turning out machine-made "averages" therefrom.

The Conscience clause was condemned as a backward step and the huge pile of "smallpox fuel" which is steadily heaping up under it, in readiness for another epidemic, was noted with apprehension.

Dr. Cousins also called attention in a timely way to the fact that the greater part of drug-taking is done by the people themselves, without the sanction of a physician, and prophesied a marked decline in the amounts of medicine used as the laity—and he might have added, to be perfectly fair, the profession—became more intelligent. He hoped ere long to see every alleged specific protected by the Government stamp compelled to display upon its label an exact formula of its contents; falsification of which, if proved by analysis, would annul the patent.

The Association is about to be asked to take a hand in the fight of the members of the College of Surgeons for representation upon its Council, notice having been given of a motion to that effect. It seems hardly likely that this body, however, will consider the matter within its province.

AUGUST 3D.

Our forebodings based upon yesterday's small enrolment have been fulfiled and the Sections this morning are thinly attended, such members even as have come seeming more immediately interested in the excursions and entertainments, and no wonder in this scorching heat in a land where they don't know the A B C of how to keep themselves cool. No ice within miles and the

starchiest and stupidest of drinks—nothing with a gleam of cooling inspiration in it!

No badges are worn at these meetings, which is a pity as they form pleasant souvenirs of the place. Not that they are in the least needed, for the fine, professional air of the "M. R. C. S. L. R. C. P." can be recognized across the street. The gathering fairly glows with refulgent respectability and the suavely judicial manner of the consultation-room surrounds even each separate individual member as with a halo.

The Local Committee has been most generous of its labor in arranging a perfect swarm of excursions to the Isle of Wight, Winchester, Salisbury, and a score of places of interest in the neighborhood.

The general meetings are held in the Great Hall of the imposing Town Hall, hung round with the banners of the Sea Kings, Nelson, Anson, Collingwood, Drake, whose very names bring the blood to even an American cheek, heroes as they are of our common race.

The sections are held in the committee rooms of the Town Hall and in various rooms in the neighborhood, very convenient of access but a little incongruous at times in sound at least. The Pathological, for instance, is held in an infant school in the delicately appropriate region of "Salem Street" but how much better the Section on Pediatrics or even Obstetrics would have fitted there. The Section on State Medicine is held in a gas company's office, where it is to be hoped their discussions will not make the meters register any faster than they do at present.

The Drug and Appliances' Exhibit, which we frankly label as the advertising display, is here dignified by the title of "Annual Museum" and a huge catalogue of the exhibits is printed by the Association.

SCIENTIFIC MEDICAL JOTTINGS FROM AMERICAN TROPICAL COUNTRIES.

HOG-CHOLERA IN BRAZIL.

THE declaration of Drs. Reed and Carroll of the Army Medical Department at Washington that Sanarelli's supposed bacillus of yellow fever is really the bacillus choleræ suis gives special medical interest to the existence of that disease in countries like Brazil, where yellow fever is endemic, and in South-American countries generally. In the *Revista Medica de S. Paulo*, Brazil (a Portugese medical monthly), for June 15, 1899, Dr. Bonilha de Toledo reports the conclusions of some interesting work in the bacteriology of the disease done at the Bacteriological Institute of the State of St. Paul.

The investigation puts beyond all doubt the existence of hog cholera in the neighborhood of S. Paulo, and gives some interesting details of the biology of the specific bacillus of the disease. The germ isolated from the hogs can by cultivation in artificial media in pure culture, be made to lose its virulence practically entirely, so that susceptible animals are able to tolerate without inconvenience "relatively enormous" injections of the microbe. Its virulence on the other hand can be enormously increased by passage through such animals as the rabbit and the guinea-pig. Hog cholera, as observed in Brazil, is the same disease as has been described by French writers under the name of pneumo-enterite. [Professor Sanarelli seems to have demonstrated in last week's MEDICAL NEWS that it is a laboratory error that has led the American investigators to declare that the bacillus choleræ suis and his bacillus icteroides are the same micro-organism.]

CAUSE OF YELLOW FEVER AT MONTEREY, MEXICO.

The result of the investigation of the origin of the yellow-fever epidemic of last year at Monterey was announced in the *Boletino del Cons. Sup. de Salubridad*, Mexico, No. 6, 1899. The infection came from the port of Tampico where yellow fever is proclaimed to be endemic, and was carried by way of the railroad. The commission thinks it has demonstrated that merchandise and freight of various kinds as well as sick human beings can carry the contagion.

With regard to the pathology of yellow fever two lesions especially are insisted on that have not heretofore been given a sufficiently prominent place in the morbid anatomy of the disease. In many cases there exists an exquisite fragmentation of the myocardium and in nearly all an intense fatty degeneration of the kidneys. The microscope shows large zones of renal steatosis in the midst of which there is complete destruction of the uriniferous tubules, in fact the secreting substance and all the essential parts of the kidney proper are reduced to a disorganized mass of fatty material.

In the bacteriology of the disease the commission finds a great liability to secondary infections. This has, of course, been already very much insisted on by Sanarelli himself. They found the bacillus icteroides with the biologic and morphologic characters indicated by Sanarelli, and besides this micro-organism practically always ordinary forms of staphylococcus, streptococcus, the colon bacillus, and proteus, etc., which must be considered as nearly always playing an etiologic rôle in the production of certain of the symptoms of yellow fever.

THE BACILLUS OF YELLOW FEVER AND MOLDS.

Last year Dr. de Lacerda pointed out, as we reported at the time in the MEDICAL NEWS, that a very remarkable symbiosis existed between certain molds and the bacillus icteroides. He saw in this symbiosis the probable reason why yellow fever infects especially the sea coast, and generally damp localities as on shipboard, for it is in such places that molds grow most luxuriantly. Further study has confirmed his original conclusions (*Brasil Medico*, No. 20, Rio de Janeiro, 1899). Not every kind of mold favors the growth of the bacillus icteroides, however, but especially a brownish form of aspergillus. Dr. de Lacerda has found in a tube of agar originally inoculated with bacillus icteroides, but which seemed to remain sterile and which was practically thrown aside in the laboratory, that at the end of a year, examined by chance, there was found a rich growth of this special brown form of aspergillus. In the meshes of the mold were forms of bacillus which proved on further investigation to have all the morphological and biological characteristics of the bacillus icteroides.

It is assumed that the gelatinous mass formed by the aspergillus makes a habitat for the bacillus icteroides outside the human body. This is interesting as one of the very rare cases of plant parasites acting also as human parasites. Observation in the neighborhood of Rio Janeiro has shown that the most common mold in the summer time is precisely the aspergillus, while in winter only pencillium and mucor are to be found which would give a new reason for the failure of yellow fever to be epidemic during the cold weather. This is not the only interesting biological relation between the two micro-organisms, for further study seems to show that the bacillus icteroides and aspergillus are affected in a very similar manner by meteorological conditions generally.

YELLOW-FEVER DISTRIBUTION THROUGH THE AIR.

Professor Sanarelli, commenting on this work of Dr. de Lacerda (*Clinica Moderna*, No. 26, 1899), says that yellow fever is one of the diseases that seems beyond doubt to be spread through the air and not to require direct contagion. In this symbiosis with molds, a symbiosis that may preserve the bacillus icteroides, as has been shown for long periods of time, there is to be found a ready explanation of one method at least by which it might find its way into the atmosphere and be easily carried about entangled in the feathery meshes of the mold.

IS SANARELLI'S BACILLUS ICTEROIDES A SPECIFIC PATHOGENIC MICRO-ORGANISM?

The conclusions of Dr. London's work on the bacillus icteroides, though done at St. Petersburg and published in the last annual report of the Russian Society for the Care of Public Health, seem to deserve a place in this column. He was asked by Professor Lukianow, the well-known head of the Imperial Institute at St. Petersburg to study a pure culture of the bacillus icteroides. He finds that Sanarelli's bacillus must be considered as a particular species of bacterium endowed with undoubted pathogenic properties for various animals. Microscopic examination of the organs of animals that died after injections of pure cultures showed a state of congestion and a fatty degeneration of the cellular elements. The bacilli were found either isolated or collected in groups sometimes within, sometimes outside of the capillary vessels. London observed the change of form under changes of temperature, which Sanarelli considers so characteristic of his bacillus icteroides.

SOCIETY PROCEEDINGS.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-seventh Annual Meeting, Held at Portsmouth, England, August 1, 2, 3, and 4, 1899.

FIRST GENERAL SESSION.

OWING to the illness of the retiring president, SIR THOMAS GRAINGER STEWART, DR. ROBERT SAUNDBY, president of the Council, took the Chair, and introduced the president-elect, DR. JOHN WARD COUSINS, who was enthusiastically received. He chose as the subject of his address,

THE CENTURY'S PROGRESS IN MEDICINE AND SURGERY.

He reviewed the progress of medical science during the century just closing, saying in part: The great characteristic of the beginning of the century was the growing influence of new methods of research, and the declining power of theoretical speculation and abstract reasoning. The brilliant researches of John Hunter, and the results of his extraordinary industry and patient study had given a great impulse to the study of anatomy and pathology. His teachings are recognized as the foundation of British surgery. Scotland aided in the evolution of the healing art, and the fame of Cullen extended far beyond the British Islands. In 1828 John Abercrombie published his famous work on the diseases of the brain and spinal cord. In Ireland Robert Graves was an eminent clinical teacher and expounder of the phenomena of disease. William Stokes will ever be renowned for his researches and writings on diseases of the heart and chest. In France medical science was roused by the researches of Bichat in anatomy and physiology. Soon after the medical world was startled by the new methods of physical diagnosis introduced by Laennec. In 1840 Bright described the disease of the kidney which is still known by his name; and not long after Bell and Marshall Hall made it possible by their labors to discriminate diseases of the spinal cord.

Let me remind you that the first years of the century were marked by the rapid and complete triumph of vaccination. Jenner's first treatise appeared about 1799 or 1800. In 1802 the question of vaccination as a preventive remedy for smallpox was brought before Parliament. The new method spread rapidly over England, then to Germany, France, Italy, America, and the whole civilized world. It is a well-known fact, however, that this remarkable acceptance of vaccination at this time was due to the efforts of public-spirited men rather than to the members of the medical profession. Many of the doctors of that day considered the practice as medical quackery, and even charged the vaccinators with flying in the face of heaven. Yet at this period smallpox was a frightful scourge. Throughout the Eighteenth Century nearly every human being suffered from the disease, and the mortality was often appalling. Jenner died in 1823, still doing battle with the foes of progress, and in the hour of victory. We can now look back upon the experience of 100 years and accurately estimate the value of his great discovery. Since the introduction of vaccination there has been a steady diminution in the death-rate caused by smallpox. During recent years the disease has been almost exterminated by infant vaccination and revaccination in the later periods of life. Wherever an outbreak has occurred, the unvaccinated are attacked in much greater proportion than the vaccinated; and the mortality among the unprotected is much higher than among those who have submitted to this safe and protective remedy. The recent modification of the vaccination laws is regarded

almost universally as a very unsafe and retrograde change and there is reason to fear that sooner or later there may be another outbreak of the disease. I am confident, however, that the voice of the medical profession will never cease to sound the alarm, and that our great Association will never hesitate to put forth all its influence and strength until the adversaries of sanitary progress have been defeated, and the old enemy slain again at our gates.

During the early years of the century the development of the various industries rapidly caused a migration from the country toward the provincial centers, and for this increase of their inhabitants there was very little accommodation. I need not remind you of the wretched state of the houses of the working population in those days—the narrow courts, the stifling slums, the unwholesome factories, the neglect of cleanliness, and the total absence of any rudiment of sanitation. It is not surprising that, under these conditions, disease, deformity, moral and physical degeneration were the results. The bills of mortality of London at this period sometimes reached 50 to 60 per 1000 living. In 1834 the Legislature commenced action in the sanitary interests of the people. Soon after a national system of registration was introduced, and the causes of death were certified by medical men. Acts of Parliament were also passed to give power to town authorities to provide water-supply and drainage. Pioneers in sanitary reform arose on every side, while fresh revelations of neglect startled the intelligent people, and a loud demand arose for increased legislative control. But there was an outcry from the grasping holders of vested interests, and from the prejudiced of every class of the community, against the growing power of sanitary reform and every earnest effort to cast out preventable disease. The dreadful epidemic of cholera in 1848, and the largely preventable horrors and sufferings of the soldiers in the Crimean War in 1855, were productive of still further beneficial legislation.

The name of Florence Nightingale will ever be associated with the evolution of hospital reformation in this country. She roused not only the civilized world, but also the professors of the healing art, and the loud demand for hospital reform which has been extended through the length and breadth of the land can be fairly traced to the mental power and splendid devotion of Florence Nightingale.

The early part of the century will ever be recognized as the birthtime of modern pathology. The teaching of John Hunter was a long way in advance of his predecessors and he was the first to recognize that all the processes of the organism belonged to biological science. He saw that disease was only a deviation from health and that both conditions were regulated by the same vital laws. The manufacture of the acromatic compound microscope in 1830, made possible the discoveries of Schleiden in vegetable tissues, and those of Schwann in the cellular structure of animal bodies, but we are indebted to Virchow for exhibiting histology as the real instrument for unfolding the deep mysteries of disease. He practically gave the medical world a new pathology founded upon laborious observation and experiment. Every kind of organic structure and every new formation, he announced could be traced to a vital source.

An inquiry into the early history of many branches of science clearly indicates that old speculations concerning obscure phenomena have often in the long run proved to be real anticipations of future progress. About 1840 Watson ascribed the wide diffusion of influenza and other infectious fevers to the presence of minute substances: "Myriads of animalcules may come in contact with the mucous membrane, and exercise a poisonous influence on the system. The gaseous fluid which surrounds this planet teems with living atoms, and these atmospheric infusoria probably congregate in masses sufficient to render noxious the very air." The theory of fermentation enunciated by Professor Liebig tended at this period strongly to confirm the parasitic theory. I cannot pretend to sketch the evolution of this young science, but only to mention that this fresh light has arisen from France, Germany, and England, and that it is mainly due to the brilliant labors of Lister, Pasteur, and Koch. Lord Lister has generously expressed his indebtedness to Pasteur for his original researches; Koch has by his splendid ingenuity made the most important improvements in the bacteriological technic. No doubt they are all indebted to each other, and the world of science will be for ever indebted to them all.

We are greatly indebted to our distinguished member, Sir James Paget, for his brilliant efforts to promote research in comparative pathology. Only a few years ago the real nature of that dreadful scourge of the human race, tuberculosis, was discovered, and its intimate association with the same disorder in domestic animals was clearly brought to light. Tubercle had been examined by the best observers in the civilized world, who, with a remarkable unanimity, pronounced the opinion that it was so indefinite in structure that it could be recognized as much by negative as by positive qualities. But in 1882 the whole pathology underwent a great revolution by the demonstration of the life-history of the tubercle bacillus. The disease, occurring in any tissue or organ, is now universally regarded as a specific disorder, and the bacillus the cause of the morbid changes. The inheritance of constitutional peculiarities, the liability to chronic inflammations, and the susceptibility to external influences are now regarded as conditions which help the microbe to establish itself within the body. Still these factors are not less potent because the specific characters of tuberculosis have been revealed.

In 1894 the bacillus of the plague was found in the blood of a patient. As long ago as 1881 Ogston discovered micro-organisms in acute abscesses, but there are still many unsolved problems around septicemia. Ross and Manson have traced malaria to a parasite which has the power of assuming a latent condition within the human body while it is propagated outside of the human body. I refer to these facts only to show the great impulse bacteriology has given to the study of the intimate connection between the diseases of mankind and the diseases of animals. What may we

expect from this young science in the future? We are only touching the fringe of its possible revelations.

A hundred years ago the physician enjoyed both professionally and socially a far higher position than the surgeon. Medicine was regarded as a science, but the leaders of that day looked down upon operative surgery as a reproach to the healing art. John Hunter spoke of operations as only humiliating examples of the shortcomings of the medical science. It is not surprising that the knife as a remedy was greatly dreaded, and the prospect of an operation caused in many patients great mental depression. The after-treatment, too, was often extremely painful and very roughly carried out.

The idea that some agent might be found to render operations painless appears to have engaged the attention of surgeons from the earliest times. Mechanical means were employed for compressing the blood-vessels and nerves; hypnotic anesthesia was employed by some surgeons, and opium and alcohol were freely administered to relieve the distress of very painful operations, but the results were often very unsatisfactory and dangerous. Sir Humphrey Davy at length published some researches concerning nitrous oxid. Ether had been used in medicine for many years, and it enjoyed a great reputation in chest diseases. Dr. Crawford Long, of Pennsylvania tried the vapor in some minor operations about 1840. Horace Wells, a dentist of Hartford, Connecticut, and William Morton, dentist of Boston, employed ether locally for toothache, and also to relieve the pain of extraction. Subsequently Morton experimented with ether upon animals, afterwards upon some students in his class, and then upon himself. He administered it to his patients at length, and, after many careful and anxious trials with various kinds of inhalers, he privately communicated his experiences to Dr. John Collins Warren, and requested that he might be permitted to administer ether during an operation. This was successfully done, October 16, 1846.

The discovery was carried with great rapidity to all parts of America and to the central cities of Europe. On December 24, 1846, Liston in London performed amputation of the thigh under ether anesthesia with complete success. Sir James Simpson of Edinburgh (then Dr. Simpson) took up the question with great enthusiasm. He considered that ether was not free from objection because of the large quantity required to establish insensibility, and he commenced to investigate the effects of other volatile fluids. He afterward made many successful experiments with chloroform at the University of Edinburgh.

The introduction of surgical anesthesia exercised at once a great influence on the practice of surgery and the number of operations increased in all directions. Unfortunately, the surgical world was quite unprepared for the sudden outburst of enthusiasm which followed the great discovery. At this period surgical instruments were few in number and many ingenious aids to diagnosis now universal were not then in existence. The hospitals were constructed regardless of all sanitary precautions and without any means for securing adequate light and fresh air for the safe treatment of urgent surgical cases and acute diseases. The nursing system, too, was rotten to the core. Under such conditions it is not surprising that suppuration followed almost every wound, and that septic processes were started by every operation. Again and again gangrene, pyemia, and erysipelas ran through the wards of these old buildings, and the medical officers saw clearly that these outbreaks were infective disorders and were carried from one patient to another. The terrible ravages of sepsis helped to bring about better ward ventilation and improved sanitary arrangements in many of the old buildings, and these advances helped to prepare the surgical world for the coming of the great crisis when the doctrines of Lister shook the foundation and revolutionized the practice of surgery. Lord Lister demonstrated to the world the part that living organisms play in the production of septic diseases and then exhibited the simple means by which their growth and development could be prevented. During the last quarter of the century surgeons have carried out the aseptic system in every land and in every clime, and it has given a surprising impulse to successful practice, and has developed into a world-wide blessing.

I shall now conclude my remarks with a brief reference to recent progress and the work of the future. The medical profession was never so earnest in its efforts to prevent disease as it is to-day, and it is really a fortunate thing for the world that our ranks are not getting thinner. On the other hand, the people of this country generally are growing wiser and will trust less to mysterious and puffed-up remedies. I hope the day will come when every vaunted specific protected by a Government stamp will carry a label revealing the exact nature of its composition. Bacteriology has already provided the physician with a new set of remedies; in diphtheria antitoxin has proved of marked utility; the treatment of tetanus, both subcutaneous and intracerebral, appears to have been successful in some cases. As regards tuberculosis, enteric fever, and cholera we must wait the test of experience.

The serum treatment of specific disorders has only reached the initial stage, still it is full of promise. Another step forward is the discovery of the great value of the product obtained from healthy glands in the treatment of certain disorders. The special utility of thyroid-gland substance has been well established and the most marked results have been achieved by its administration. At the same time we really know nothing about the nature of its secretion which appears so essential to the nutrition of the tissues.

The close of the Nineteenth Century will be forever memorable for the great efforts which have been initiated for the prevention and cure of tuberculosis, not only in this country, but in all civilized lands, and we sincerely hope that this united attack upon our deadly and widespread enemy will be followed by enduring benefits to the race. It is a matter of great congratulation that H.R.H. the Prince of Wales is the head of the great national association which has been formed for the purpose of arresting, as far as possible, this dreadful scourge, and

that in all the leading centers men of every class are cordially cooperating in this important movement. The tubercle bacillus does not seem to care for all the physic in the world; but we believe that in a germ-free atmosphere and pure surroundings it may be made to die.

Notwithstanding the great progress of medicine during recent years the results have been less manifest than the brilliant advances of modern surgery. There is no organ or region of the body which has not been investigated by the surgeon. Only three and a half years ago the remarkable discovery of Professor Röntgen was communicated to the scientific world and it has already proved of great value in surgical practice, having revolutionized the old methods of military surgery, and given a fresh impulse to the study of diseases and deformities of the skeleton. Noteworthy advance has been made in the treatment of hernia by the development of the operation for radical cure. Hundreds of thousands have been saved from lifelong deafness by the removal of nasopharyngeal vegetations, thanks to the discoveries of Hans Wilhelm Meyer.

The experimental investigation of the causation of human septic disease is still far from complete. Up to the present time we have no cure for sepsis when it has entered the body; still we have much reason to hope that a remedy will be found, and that the destruction of sepsis-producing organisms within the blood and tissues may be at length accomplished.

The treatment of cancer and its manifold complications is another great field for inquiry in coming years. For some time a growing impression has prevailed that the disease has been steadily on the increase. No doubt during the next few years the question will be settled. Recently some investigations have been published suggesting that the disease is due to a parasite. Local irritation is certainly a great factor in the development of cancer. Other observations have suggested that the disorder is liable to recur in particular places. A curative serum for carcinoma has not yet been discovered. Up to the present time surgical treatment yields the best results, and the earlier it is adopted the better. The pathology and treatment of cancer still bristle with difficulties. It is at least some satisfaction to know that many of the best pathologists and surgeons are diligently laboring in all parts of the world to unfold the mysteries which still surround this terrible disease.

In the coming century a stronger and broader warfare will be carried on against preventable disease. I believe there is every reason to anticipate that the death-rate of the country may still be greatly reduced, and that 10 to 12 per 1000 may be the figures of the coming century. The great hindrance to the progress of preventive medicine which we have to overcome is the overcrowded and unsanitary condition of the dwellings of the working classes. This is the field on which the great battle with infectious disorders will have to be fought out. Our warfare will not be directly with microbic life, but rather with the conditions in which specific organisms are grown. We want to see more progress in getting rid of the crowded and dirty courts in every city. These denlike homes are the arch enemies of sanitary progress in all our great centers. But the battle against disease and death will only end in disappointment unless we have something more than the force of legislation and the unceasing watchfulness of a complete sanitary system. If we had the power of transforming the dwelling-houses throughout the land, and of establishing everywhere a perfect system of drainage, and of securing for all an abundant supply of pure water, we would accomplish but little without the help of the people themselves. Depend upon it, the basis of national health is the personal cultivation of health. We want the fathers of England to be the enlightened sanitary officers of their own household. We desire to see a wider knowledge of the laws of health and I hope the day is not far distant when they will be zealously taught in every school in the kingdom. The working classes have to learn that rest is essential to overcome the strain of daily labor, and that personal cleanliness, temperance, and domestic sanitation lead the way to higher blessings. The weekly rest when rightly used gives another impulse to sanitary progress. It promotes purification of the body and cleansing of the dwelling. What washings and scourings, what polishings and decorations herald its near approach! What an army of buckets and brushes and dust-disturbers are called out at its coming; what floods of clean water are made to remove the accumulations of the week! Yes; the weekly rest falls like the reviving dew on the hot brow of industry; it stops the wheels of labor; it soothes the brain, give rest to hands, and calls forth the highest aspirations of human nature.

Second General Session.

At the General Session on Wednesday, August 2d, it was decided to hold the next annual meeting of the Association at Ipswich. Dr. W. A. Elliston of that city was chosen president-elect.

Address in Medicine

was delivered by Sir Richard D. Powell.

He said in substance: Thinking over the best way in which to fulfil the task which I am honored to perform to-day, it occurred to me that it might be interesting to listen to a few remarks suggestive of the trend of medical opinion to-day.

We are certainly better equipped for exact diagnosis now than ever before, and possess a larger and a more precise knowledge of a greater number of diseases. The flexible stethoscope which has come almost exclusively into use within the last twenty years intensifies sound but practically obscures impulses. Thus the sense of touch in auscultation is, if I may use the phrase, in a certain degree becoming lost to us. I have known the diagnosis of an aneurism missed in this way.

Happily we already see a revival of the appreciation of the pulse in practical medicine; and the clinical habit of listening to the heart, not only with the view of hearing morbid sounds, but to estimate work value, is also of recent acquirement. The clinical thermometer is as important in bedside medicine to-day as the barometer and compass combined are in navigation, and where we are

sometimes led astray by pyrexial charts it is not the thermometer that is at fault but our insight that is imperfect. Not long ago the temperature mistaken for the disease was pursued round the dial by antipyretic medication and measures taken to the spoiling of the chart, the detriment of the patient, and the disappointment of the doctor. A better knowledge of the habits and vital history of the micro-organisms upon whose doings pyrexial phenomena so largely depend, informs us that their initial attack and greatest activity is at the lower ranges of temperature, and that the higher ranges, the results of such activity, are more or less inhibitive to their well-being. Thus we have often observed a pneumonia or an influenza treated too vigorously with pure antipyretics pursue an abnormally stormy and adynamic course.

The clinical study of anomalous fevers has gradually convinced us that in their development and full activity specific poisons may overlap one another in the same illness; thus the typical *crescendo* temperature of the early period of an enteric fever may be masked by the fluctuating pyrexia due to the toxin of an associated sepsis. A rational treatment of specific diseases must be guided by the recognition of these superfactors. The rational and most successful treatment of tuberculosis is for the most part unwittingly directed to attendant phenomena which are secondary, and which for brevity's sake we call septic. Our antiseptic treatment and our pure-air methods are mainly operative against such secondary infections. In the diagnosis of fevers we have auxiliary tests of modern design—some purely chemical, such as Ehrlich's, others furnished by examination with bacterial reagents, such as Widal's test in enteric fever, which are of considerable value in anomalous cases.

It must be confessed that bacteriology in its application to diagnosis and treatment in practical medicine is yet in its infancy; but it is a very robust infancy, full of promise. Bacteriology in all its departments is, and must ever remain, subject to expert investigation. It is impossible for the busy practitioner to find the time or to maintain the technical skill and apparatus necessary for trustworthy investigation, and it is to be hoped that the time will soon come when in every district throughout the country there will be in connection with the Public Health Department a bacteriological laboratory, where the ordinary, and even the extraordinary, clinical tests will be at the command of every practitioner at a moderate scale of fees.

It is a matter of congratulation to see the departments of research and clinical observation approaching to closer communion in our great hospitals, a cooperation which cannot but be to the great advantage of the physicians, and I venture to think scarcely less so to the research expert. We are thus acquiring daily a more accurate knowledge of organized poisons and we are interpreting better the phenomena they produce.

It has long been clear to every observant physician that we carry about with us in our accessible mucous tracts and especially in our naso-oral and respiratory passages, samples of the organisms specific to many diseases. We are tenanted by these varied organisms in small colonies or singly, rendered inert only through want of opportunity. Let a period of depression come over us, involving some slight change in our blood or tissue, and one or other of these organisms may receive the opportunity for aggressive cultivation. We virtually know that this is so in the case of a common cold whose bacteriology no one, so far as I am aware, has yet condescended to work out. Yet it is the type of a large number of more important diseases, and carefully investigated it would, I believe, be fruitful in side-lights upon their etiology and prophylactic treatment. There are many people of somewhat feeble vitality whose complaint is that they are constantly catching colds. Such attacks are due probably to the cultivation of successive crops of an ever-present organism. We have little power in attacking the organism; we might as well do battle with a sunbeam. Our treatment is to fortify the host.

I will only discuss the question of serum-therapeutics from the side of results achieved in the form of additions made to our therapeutics. It is already an immense achievement if we have acquired the knowledge that every infection requires a separately prepared serum for its treatment. It explains many of our failures and gives promise of adding to our successes. It has for some time been recognized that infective endocarditis has a manifold microbic pathology—streptococcus, staphylococcus, pneumococcus, gonococcus, are some of the organisms concerned. It is useless to employ an anti-streptococcus serum for a pneumococcus infection, and even the two organisms, streptococcus and staphylococcus, which seem to work most cordially in couples, require a separate treatment. We must push our diagnosis further to include a recognition of the precise organism or organisms which have obtained lodgment in any given case. We are indeed only at the dawn of serum-therapeutics and many mistakes will have to be retrieved, many apparent steps forward retraced, in the sure but slow advance in this new departure of therapeutics. Although Pane's antipneumococcic serum will protect a donkey or a rabbit from the evil consequences of a strong dose of pneumococcus infection, it has not as yet come into practical use in the human disease. I have recently tried it in two cases without result. This may be due to three causes. In the first place it is difficult to use the serum early enough in the disease, and, secondly, the most severe cases in which at present one feels disposed to try the remedy are most generally complicated with some other infection, so that the pneumococcus in the sputum does not signify the sole—perhaps not the most important—element of danger in the case. Thirdly, the doses employed by Pane have been very large, so large that one shrinks from introducing in such bulk an unknown or imperfectly accredited element into any case not already desperate. In all probability the want of success in the antitoxin treatment of erysipelas, puerperal fever, and allied affections, including infective endocarditis, may be accounted for by the presence of more than one organic infection, thus requiring, as pointed out by Behring, Pfeiffer, and Kanthack, more than one antidote.

It seems possible that we may look in the near future for considerable development of preventive serum treat-

ment in the prophylaxis of endemic diseases. Already within the past few months we have seen maturing toward successful action the researches of Haffkine and Wright and others on the means of procuring immunity from typhoid fever and plague. Indeed, the whole question of antitoxin and serum-therapeutics has only within the last five years become of practical interest to the physician, and we may expect every day to bring to light fresh developments.

It may be urged with some justice that we in this country have been behind our Continental friends in grasping the full significance from a prophylactic point of view of the discovery of a definite infective bacillus element in tuberculosis, which was made seventeen years ago and anticipated seventeen years previously. But to set heredity at naught, to regard climatic considerations as of no importance, and to state that the disease is always acquired by direct contagion or infection is, in my opinion, to ignore much that is true, and to magnify that which should be carefully guarded from exaggeration. We cannot, of course, prevent consumptive people from marrying; but the advice of the family physician should be discouraging to such alliances, which are unfortunately often prolific.

But whilst on the one hand advising every ordinary measure of cleanliness, avoidance of dust, and proper disposal and disinfection of sputum, we may, and indeed must, avoid all exaggerated statements calculated to alarm the public as to the contagion of phthisis, the evidence of which, except under the most experimental conditions alluded to, is extremely slender. It is remarkable that two at least of the most deadly of disease microbes, tetanus and anthrax, should be normal inhabitants of the soil, and yet how comparatively scarce these diseases are, and, having arisen, how communicable. It would seem that, as is the case also probably with malaria, whilst the ultimate source of the disease is vegetation in the soil, yet a greater virulence and activity is attained, and for a short time maintained, by cultivation in the human body, or in that of certain other warm-blooded animals. General sanitation and cleanliness is our first line of defense against them all. Wherever the conditions of insanitation, dampness, deficient sunlight, and the prevalence of favoring diseases are present there aggressive activity may be again looked for.

Section on Medicine.

First Day—August 2d.

The Section on Medicine was opened by the President, Dr. J. Mitchell Bruce. He confined himself to outlining the program, emphasizing, however, the importance of two topics which were to come before the members for discussion, one being the "Examination of the Men and Boys Who Were Admitted into the Services," and the other the "Preventive and Remedial Treatment of Tuberculosis." The former was peculiarly appropriate for discussion in Portsmouth, and the latter would be full of interest on account of the numerous winter health-resorts in Great Britain, and because of the number of well-qualified speakers who were to take part in the discussion.

In the absence of Sir Dyce Duckworth, the president read his opening contribution to a discussion of the medical tests required at present for admission to the public services. The factors of the eligibility of candidates, both on account of physique and the power to pass examinations, were generally discussed and the causes of the rejection of defective candidates reviewed.

Professor Osler, who followed, said that the physical examination of candidates should take place earlier in the course of their training, and alluded to the presence of a cardio-respiratory murmur, a pulmonary systolic murmur, and adolescent albuminuria as more common causes of their unnecessary rejection.

Surgeon-General Muir and Surgeon-General Cuffe spoke of the question from the military side, and on the whole supported the *status quo;* while Surgeon-Colonel Welch thought that the most suitable men were not obtained for the army on account of the literary requirements. The President suggested that the following resolutions should be sent up to the Council, requesting that they be submitted to the War Office: "That the physical examination should precede the educational; that soldiers should not serve in the tropics until twenty-two years of age, and that the question of the physical standard required reconsideration." These resolutions were unanimously adopted.

Section on Surgery.

First Day—August 2d.

The Sectional work was opened by the President, Mr. H. T. Butlin, who outlined the subjects for discussion, calling especial attention to the importance of gunshot wounds in civil life and to the high percentage of soldiers who are disabled from duty on account of venereal disease.

An opening paper on

The Diagnosis and Treatment of Gunshot Wounds of the Abdomen

was read by Colonel Stevenson, Professor of Military Surgery at Netley. Civil practice had been freed from the dread of interference with a serous membrane. Military surgeons had been slower in recognizing the capability of modern surgery in cases of gunshot wound of the abdomen, and for the following reasons: The procedures must be carried out in field-hospitals; the personnel of these hospitals was kept as low as possible; the work done in them was performed at high pressure; wounded men were often left on the field of battle a long time before being picked up, and the military surgeon's mind was influenced by the feeling of the "greatest good to the greatest number." When patients were healed by rest and opium, the cures were probably not more than 1 per cent. of those diagnosed. When a bullet traversed the abdomen it might be assumed that either extravasation of intestinal contents or hemorrhage, or both, had occurred.

A fatal issue was certain in either. The indication was quite distinct; the abdomen must be opened, the intestines sutured, and the peritoneum cleansed. The symptoms of hemorrhage and of extravasation of intestinal contents were analyzed and discussed. Hemorrhage results from the following injuries, in point of frequency: Rupture of the liver, spleen, kidneys, small intestines, and large intestine. The symptoms of extravasation are misleading, irregular, and inconstant. The onset of sudden meteorism, upon which so much stress had been laid was considered of no value. The absence of liver dulness might be observed when no rupture of intestine had occurred, and liver dulness might be present when there was much free gas in the peritoneal cavity. The results in recent campaigns were mentioned. In the Spanish-American war all patients operated on died. In the Græco-Turkish war 1 case of hemorrhage, and 1 of injury to the liver terminated in recovery, 1 of wound of hollow viscera in death. In the Tirah campaign 5 patients were operated on and all died. The statistics of Morton of Philadelphia were more encouraging. In 234 cases occurring in Europe and America, the mortality was 58.9 per cent. Coley's statistics showed a death-rate of 53.9 per cent. if operation was performed within twelve hours, and 77.3 per cent. if performed after twelve hours. When a wound of the intestine was found it was best treated by (1) simple suture in two layers, one for the mucous membrane and one for the peritoneum; (2) the method of Maunsell; (3) Murphy's button.

Dr. Ward Cousins pointed out that the chances of success depended on early operation as soon as the diagnosis of internal injury had been made out. The diagnosis was not always easy. Perforation with very little extravasation might not cause urgent symptoms; on the other hand, severe contusion of the abdominal wall might be followed by great collapse. Every case must be left to the judgment of the surgeon. When operation is performed it is best to enlarge the wound of entrance and to use as retractors stitches passed through the edge of the wound and held by assistants. The methods of treatment he preferred were simple suture by fine silk and the Murphy button.

Major W. C. Beevor quoted the experience of Colonel Whitehead and himself in the Tirah campaign. The number of the wounded was very large; all water within access was contaminated by the urine and feces of men and animals. He quoted cases showing the enormous difficulties in the way of carrying out adequate treatment. He drew attention to the enormous advantage obtained in the treatment of collapse, by the preliminary irrigation of the peritoneal cavity.

Surgeon-General O'Dwyer expressed the belief that operation on the field of battle was impracticable. Unless patients could be dealt with as in civil life it is better not to operate.

In reply Colonel Stevenson regretted that in the Tirah campaign the conditions did not approximate to those existing in civil life, but felt sure that with the new equipment the measures suggested as being necessary for the adequate treatment could be efficiently carried out.

Section on Obstetrics and Gynecology.

First Day—August 2d.

The President, Dr. G. Granville Bantock, made a plea for conservative work. He said that he had viewed with much concern a growing tendency to resort too quickly to the knife; in other words, a *cacœthes operandi*. There should be greater reliance upon measures of a more simple and conservative character. He mentioned several instances that showed the bad results of too hasty operation.

The discussion was opened by Dr. Herbert Spencer, who read a paper on

The Treatment of Fever following Delivery, with Special Reference to Serum-Therapy.

Dr. Spencer distinguished four groups of fever following delivery; the first, often called "one-day fever," due to emotion, copremia, or other transitory cause; the second, due to complications which are not referable to the labor, including such febrile affections as influenza, scarlet fever, acute phthisis, and typhoid fever; the third, due to infection from preexisting pelvic lesions, such as pyosalpinx, appendicitis, etc.; the fourth, due to external infection, "puerperal fever," as we understand the term. Recent observations have shown that puerperal fever may have its origin in a number of micro-organisms; thus Whitridge Williams, among twenty-six cases, found streptococci, staphylococci, colon bacilli, gonococci, anaerobic bacilli, diphtheria bacilli, gas bacilli, and typhoid bacilli. In discussing the prophylaxis of puerperal fever, Dr. Spencer expressed the opinion that it is not necessary for a medical man to abstain from practice when attending such cases, as thorough disinfection will immediately enable him to attend other women with safety. After dealing with the question of local and operative treatment, the speaker pointed out the methods of remotely influencing puerperal fever, such as the nuclein treatment, saline infusion into the cellular tissue, and intravenous injection of antiseptics. Coming to the serum treatment, it was pointed out that a large number of observations had now been made upon its use, over 350 cases having been collected by a committee of the American Gynecological Society, and among these cases there was a mortality of thirty-three per cent. Probably the natural mortality was not greater than this. The conclusions to which Dr. Spencer had arrived were: (1) That as usually applied serum-therapy in the treatment of puerperal fever has no scientific basis; (2) that it has not lowered the mortality; (3) that it usually lowers the temperature and sometimes improves the general condition; (4) that its use is not free from danger.

Section on State Medicine.

First Day—August 2d.

The Presidential Address in this section was delivered by Dr. George Wilson who spoke with great frankness on the relations of bacterial research and methods of treatment to preventive medicine. He began by saying

that Pasteur's prophylactic inoculations are based on errors, and are the the outcome of illogical inductions, every one of them. The indiscriminate maiming and slaughtering of animal life with which these bacteriologic methods of reseach and experimentation have been inseparably associated cannot be proved to have saved one human life or to have lessened in any appreciable degree the load of human suffering.

There are certain infectious diseases one attack of which protects, as a rule, against any future attack. This can be more emphatically said of smallpox than of any other disease. That is why inoculation was practised for a time, and was so successful as far as the individual was concerned. Jenner concluded that if he inoculated with the matter contained in the vesicles of cow-pox instead of with smallpox matter he might be able to confer immunity against smallpox. He made the further discovery that he could confer immunity from smallpox by vaccinating from person to person. He made it clear that cowpox or vaccinia was a modified form of smallpox. Vaccination, therefore, induces vaccinia and vaccinia protects against smallpox because it is a modified form of the disease. Unlike smallpox itself it does not confer absolute immunity, as Jenner imagined it would. It only confers a modified degree of protection against smallpox because vaccinia is only a modified form of the disease itself by transmission of the virus through the cow or calf.

It has been admitted by Pasteur, Koch, and all of their followers that their methods of prophylaxis and cure are based on Jenner's happy inductive inspiration. In the first place, bacteriologists have failed to discover any pathogenic microbe either of smallpox or vaccinia which they can isolate with certainty. The few pathogenic microbes which bacteriologists have discovered associated with human disease, and which they can isolate and cultivate, are those of tuberculosis, diphtheria, enteric fever, cholera, and plague; but all these are found associated with necrosed tissues, and it is open to argument whether, instead of being labeled the unconditioned *causæ* of those respective diseases, they may not be performing a benign function in changing the necrosed tissues into harmless products, just as various kinds of micro organisms are necessary to change filth and all dead organic matter into harmless matter. Then, again, vaccine lymph must be taken from the vesicle at a certain stage of development. When successfully used, as in vaccination, it is followed by manifestations of a definite disease known as vaccinia, with a well-defined incubation period and well-defined and characteristic symptoms—a varying amount of pyrexia, tumefaction at the point of vaccination—the vesicular and pustular stage.

In contradistinction to these facts, the serum of an immunized animal confers at the utmost only a doubtful and short lived immunity so doubtful as to be discarded altogether, and as a cure for smallpox it is of still more questionable efficacy. It was on these grounds that the speaker reiterated his statement that there is no legitimate analogy between Jenner's great discovery and these newer methods of prophylaxis or cure which are based on that discovery.

The medical profession has misled the public as to the cruelties and horrors which are perpetrated on animal life. No one who knows Lord Lister could accuse him of wilful misrepresentation, but when he stated, as he did in his speech at the opening of the bacteriological laboratory in Liverpool last year, that the actual pain involved in these experiments is commonly of the most trifling description he was guilty of a *suppressio veri* of the most palpable kind which could only be accounted for at the time by his ignorance of the actual facts. Admitting that in the mere operation of injecting a virus, whether cultivated or not, there may be little or no pain, the cruelty lies in the after-effects. The animal so innocently operated on may have to live days, weeks, or months with no anesthetic to assuage its sufferings and nothing but death to relieve.

And what triumphs has bacteriology achieved in stemming the tide of human disease on these empirical lines? Pasteur's antirabic vaccination is, as many believe, a delusion. Koch's tuberculin cure for phthisis has long since been labeled as worse than worthless. As a test even for bovine tuberculosis tuberculin possesses only a secondary and not a specific value. The much-vaunted antitoxin cure for diphtheria does not command the universal approval of even the physicians of the metropolitan fever hospitals. The serums used for the treatment of other diseases—such as the pneumococcic serum, the serum used for puerperal fever, and Sanarelli's serum for the cure of yellow fever—are all of them allowed to slip into the lap of forgetfulness.

The bacteriologist so dominates the public press that we almost seem to live in a bacillus stricken world. And so far as preventive medicine is concerned bacteriology has rather led us on false lines in assuming that the pathogenic microbe of any disease is the *causa causans* of that disease. We know that there are certain diseases which are notoriously infectious, therefore we isolate. We know that there are others which breed on filth, therefore we say be clean and insist on cleanliness of house and home, of the water we drink, of the food we eat, and of the air we breathe. Bacteriology has assisted, and largely assisted, preventive efforts at disinfection, isolation, and so on, but it can never confer immunity against disease except by using minimal doses of the virus of that disease, and that virus to be effectual can only be cultivated and bred in the living body, not cultivated artificially in organic media. We can only fight phthisis on the old lines, by improving heritage when that is possible, by improving the homes and conditions of life and labor which are always possible and always call loudly for interference, but this hunt after the tubercle bacillus is the insanest crusade ever instituted on illogical lines. The physician can never cure, he can only direct and assist Nature in eliminating the *materies morbi*, whatever it may be.

The whole of bacteriological theory and practice is steeped with commercial interests. Behring has patented his diphtheria antitoxic serum on the Continent; Koch for years has made a princely royalty out of his tuberculin. Little Denmark has boomed her butter trade through tuberculin. Why is Germany crowding itself with sana-

toria for consumptives? Just because Germany in 1889 passed an Act that every German with an income of £150 or less must insure against sickness or old age. Last year the number of Germans so insured amounted to over 11,000,000, and these insurance societies, to save their coffers, and receive their insurance subscriptions so long as they can, start these sanatoria in self-protection. That may be a great argument for the establishment of sanatoria, but it is also a great argument for the establishment of thrifty German ways.

Dr. E. Seaton introduced a discussion on

RECENT VACCINATION LEGISLATION AND THE PREVENTION OF SMALLPOX.

In every case, he urged, there should be a report as to vesiculation and marks. Medical officers of health were, of course, anxious to isolate the earliest cases of smallpox, for which there should be suitable hospital accommodations, one of the most urgent needs of the present day.

Dr. C. R. Drysdale thought the compromise of last year had satisfied very few people. The German Government had entirely eradicated smallpox since 1876, when the compulsory vaccination of infants and the revaccination of children aged 12 was enacted, and recommended that this admirable system should be adopted as soon as possible in the United Kingdom. Dr. Groves said that the Act of last year had caused a great awakening in the minds of members of the profession, especially of the public vaccinators, who now took hygienic precautions with respect to the patient and the patient's dwelling. The difficulty of the private practitioner in obtaining lymph is great; the Local Government Board now refuses to supply him with lymph. We could not in this country obtain that absolute protection against smallpox which exists in Germany until revaccination at adolescence is rendered compulsory. Mr. H. May said the present Act is good in that it is increasing the number of vaccinations and the fees of vaccinators, and has undermined the position of the antivaccinators.

Dr. Sinclair Holden was of the opinion that glycerinated calf lymph deteriorates during the hot weather.

Section on Tropical Diseases.

First Day—August 2d.

George Thin, the president, in his opening address discussed the mosquito theory of malaria, and the establishment, in England, of two new schools of tropical diseases. He said in part: The causation of malarial fever by insects was referred to by Nott in 1848 at New Orleans as something already known, while in 1883 King published in America an excellent exposition of the mosquito theory. This theory was again suggested by Laveran in 1891, and also by Flügge in the same year. In 1894 Manson brought this problem prominently before medical men in this country, and urged that a mosquito theory was the best calculated to explain the various conditions of the problem. His suggestion was that the female mosquito fills herself with infected blood, lays her eggs some days later, and dies beside them. The water then becomes contaminated with the spores of the parasite of malaria, through which they might be taken into the human body, or might be breathed in the dust of dried-up pools, or the larvæ coming out of the eggs might eat it with the body of the mother; or the ground might become infected by mosquitoes containing the parasite falling and dying on it. King, Laveran, Bignami, Mendini, and Koch, on the other hand, considered that the infection is conveyed by the direct bite of the mosquito. Other observers have mentioned conditions which seemed to render a mosquito theory improbable. It was pointed out to me, for example, during a visit I paid to Sicily a few years ago, that a very narrow line separated the fever from the free-fever zone, whilst mosquitoes prevailed equally in both. Ross' discoveries at once and forever removed these objections. From the time he showed that to inoculate sparrows with proteosoma by the medium of the mosquito a special mosquito was necessary, it was evident that the next thing to do was to discover whether some particular genus or species of mosquito was the host of the parasite of malaria, and in August, 1897, Ross, when examining two "dappled-winged" mosquitoes which had been fed on a patient who had crescents in his blood found in the middle intestine certain round bodies which contained malarial pigment and which he rightly regarded as a development of the parasite.

While Ross was working in Calcutta with proteosoma, Grassi, during the summer of 1898, made an exhaustive study of the mosquitoes that prevail in different parts of Italy, and he found that there were many places where culex pipiens, the predominating mosquito, was common, but in which there was no indigenous malaria; whilst in places where malaria occurs he found a large mosquito, called by zoologists anopheles claviger. This species, characterized by four spots on the wings arranged like a capital T, may, he says, be defined as the true talebearer of the presence of malaria. Anopheles claviger bites sometimes during the day and night, but mostly half an hour before and half an hour after sunset.

Bignami's, first experiments in support of his theory of the direct inoculation of malaria by mosquito bites were made in 1894. The results were negative. Other experiments in 1898 also had a negative result; but guided by Grassi's information, mosquitoes were first brought on the 10th of last October from Maccarese, where fever prevailed, and were identified by Grassi as culex pencillaris, culex malariæ, and anopheles. During the last days of October the subject of the experiment began to suffer from symptoms of fever, which developed in an unmistakable manner on November 1st, and was cured on November 3rd by hypodermic injections of quinin. By November 7th the patient was perfectly free from fever, and rapidly regained his appetite and strength. On November 2d the blood carefully examined gave a negative result. On the 3d a few young ring shaped parasites, moving or discoid, without pigment, with characteristic appearances of the summer-autumn fevers, were found, increasing in the course of the day and being very numerous in the afternoon, when very fine granules of pigment were found on the edge. Dried and stained prepa-

rations showed the characteristic appearances of the parasite. In the district in Rome in which the experiment was carried out there had not been a case of spontaneous fever within the memory of medical men, the center of Rome being absolutely free from fever. The type of fever was that which prevailed at Maccarese, from whence the mosquitoes were brought. This result has since been amply confirmed by further experiments by Bignami and Bastianelli, and it has now been conclusively shown that anopheles may be made to bite a man suffering from malarial fever, and if then kept at a proper temperature (30 C) for the requisite number of days to allow the sporozoites to be present in the salivary glands, and then made to bite a healthy man who is free from malarial fever this man will, after the regular incubation period, develop malaria, and it is important to note that the parasite so conveyed from man to man through the mosquito retains its specific type. It further results from their experiments that very few bites are sufficient to convey fever; probably a single one sufficing. What is important is the species of mosquito and the stage of development of the parasite in its body. The process of development is the same as that observed and described by Ross in the proteosoma of the gray mosquito, and is common in many sporozoa. It consists essentially of increase of volume, accompanied by capsulation, which ends on the sixth day by division of the cell contents into very numerous small nuclei around which a little protoplasm is arranged, leaving a *nucleus de reliquat.* In tertain fevers it is the mature non-sporulating forms which develop in anopheles, the body of the parasite being paler, less refractive, and a little larger at the same stage of development, as compared with the crescent. The pigment is less in quantity and finer. The first phases of life in the intestine of the mosquito thus show a distinction between the crescent and tertain. The full-grown capsulated parasite is about seventy micromillimeters in size.

The discoveries of Kilburn and Smith, by which it was shown that the hematozoon which causes the Texas fever of cattle is transmitted from the tick, which is its temporary host to a second generation of ticks, by which it is again conveyed to cattle—the resemblance between the hematozoon of Texas fever and the human malarial parasite being so great that the proof that the one was conveyed by an insect was considered almost a proof that human malaria must be similarly conveyed even before it had been demonstrated that it is so—rendered it necessary to investigate whether in anopheles also the parasite is transmitted from parent to offspring. The Italian observers have, therefore, made a diligent examination of this question. So far (up to May 7th) all these experiments had been negative, and up to that date only those anopheles that had bitten human beings suffering from malaria had been shown to be capable of propagating the disease.

It will be seen from what I have related that the habits of anopheles claviger are matters of enormous importance to the human race. These insects pass the winter in human habitations and during this period their habits of migration are so much in abeyance that, although the anopheles in the dwelling-houses are found charged with human blood and contain the hematozoa of malaria, those in the adjoining stables and hen-houses do not contain the parasite. This has, of course, an important bearing on the question of prophylaxis. The genus anopheles has the palpi in both sexes about the same length as the proboscis. Five species of anopheles have been admitted for Europe. The first three without spots on the wings, are A. bifurcatus, A. villosus, and A. nigripes. The remaining two have the wings spotted—anopheles claviger (maculipennis) and A. pictus. Ficalbi thinks it is possible that the first three belong to one species. Grassi, Bignami, and Bastianelli have now extended their investigation to all the species of anopheles and have found that the parasite of malaria develops in all of them, although for Italy A. claviger is by far the most important. The anopheles claviger is widely diffused in Europe. It occurs in Scandinavia, Austria, Germany, Russia, Italy, and England. No fewer than seven species of anopheles are described as existing in the United States. Amongst them are A. punctipennis, A. claviger, and A. nigripes.

This year has seen the establishment of schools for tropical medicine in Great Britain, of which the interest and importance will, I hope, not be confined to these islands. The material requisite for the study of tropical diseases has been long utilized for the training of army surgeons, but not for civilian medical men destined to practice in the tropics. That this movement will not only be sustained, but that its scope will be largely increased, seems to me a matter of certainty. Two schools have been established, one in London at the Seamen's Hospital, and another at Liverpool, and we may confidently expect excellent work from both. But if we take into account the number of patients suffering from tropical diseases, and the opportunities of clinical study and experience, the great military hospital at Netley stands out prominently as offering conspicuous advantages with which London and Liverpool cannot compare. This school was organized and opened in 1860. If we look at the figures given in the reports of all three hospitals, it is evident that while Liverpool and Netley afford excellent schools for the study of malarial fevers, and that at Greenwich there is clearly a sufficient number of cases to enable the main features of the diseases to be studied, for the study of dysentery Netley and Greenwich afford the only available supplies, while the material at Netley far outnumbers that at Greenwich; and when we come to the most important diseases as hepatic abscess and hepatitis, in which clinical instruction is of so much importance, Netley appears to be the only school in this country in which adequate instruction can be given. The prevalence of these diseases among the civilian population in the tropics, the mortality and ill-health which they cause, and the frequent difficulty of diagnosis and treatment, render it a matter of the greatest consequence that medical men who are called on to deal with them should have instruction in a large hospital where there are groups of cases, and as Netley appears to be the only school in this country in which sufficient material for the study of

hepatic abscess and hepatitis occurs, a course there ought to be considered indispensable to every medical man who wishes or is obliged to thoroughly equip himself for tropical practice.

Whether the authorities could be brought to consider such a startling proposal as opening a military hospital to civilian practitioners I do not know. Innovations of this kind are too apt to be met with a *non possumus*, and certainly there is no precedent; but it is difficult to believe that an application for permission on behalf of medical men appointed or to be appointed to the Colonial Service would be met by a refusal. This great hospital, so long as the unfortunate supply of sick soldiers continues, is fitted to become a center of clinical instruction in tropical diseases not only for England, but for Europe.

The address led at once to a discussion of the advisability of requesting the Government to open its military school at Netley to civil practitioners for the study of tropical diseases. A number of remarks were made on both sides of the question, but a majority of those voting decided that it was inadvisable to press the matter at present, as the Government had recently lent its support to the two civil schools just opened.

Dr. G. H. F. Nuttall of Cambridge read an important and eminently scientific paper on

THE ROLE OF INSECTS, ARACHNIDS AND MYRIAPODS, IN THE SPREAD OF DISEASES DUE TO PARASITES.

After referring to the brilliant researches of Ross, Grassi, Bignami, and Bastianelli in the part played by insects in the distribution of disease, he proceeded to consider the passive and active parts played by insects as carriers of pathogenic organisms. As passive carriers the common fly is held to be the chief offender. Although unable to bite they may, from the character of their food or by their dejecta, spread several diseases — anthrax, plague, cholera, typhoid, frambosia, Egyptian ophthalmia, and Florida sore eye are capable of being thus dispersed, and experimental research has ascribed to pediculi a similar *rôle*. The evidence as to the active agency of insects was more negative. In fact, experiments made by the writer, some 250 in number, in reference to the part played in plague, anthrax, mouse septicemia, and chicken cholera, all gave negative results. In a large number of experiments made by allowing these insects to bite animals dying of the diseases named, and immediately afterward transferring them to healthy animals, not a single case of infection occurred. As regards the spread of animal parasites by insects, arachnids, and myriapods, Dr. Nuttall again considered their active and passive bearing. While serving as intermediary hosts, insects may perform a passive *rôle*, as when they are devoured by a host of the parasite they contain; and, again, an active *rôle*, when as in the case of the tick in Texas fever and malarial fever, they inoculate the parasite into a host by means of their probosces. On the other hand, insects, etc., without serving as intermediate hosts may serve as active and passive agents. As examples of their active *rôle* he cited the tsetse-fly disease, in which the infective agent is carried from one animal to another, and inoculation of the parasite itself takes place. Insects, etc., probably play a passive *rôle* in the distribution of animal parasites by the transportation of the eggs and their deposition in food, etc. As examples of this form of propagation he mentioned flies transporting eggs of tænia solium, trichocephalus, etc. Dr. Nuttall concluded by saying that in bacteriological studies what is required is more thorough work and less general theory. By microscopical specimens, photographs, and lantern-slides he showed the development of the malarial parasite.

Dr. Patrick Manson read a paper on

FILARIAL PERIODICITY.

He dwelt chiefly on the question of what becomes of the filaria during the day. In answer to this question he was able to record the results of a post-mortem examination held in February, 1897. The cadaver had been known to be the subject of filaria nocturna, and death had taken place at 8.30 A.M. (by suicide)—that is to say, just about the time the filaria had retired from the peripheral circulation for the day. Seventeen adult filaria Bancrofti were found in an enormous lymphatic varix in the pelvis. By microscopic examination of the blood it was proved that the pulmonary veins, the pulmonary arteries, the lungs and blood-clots in the heart and aorta contained swarms of embryos. The brachial vena comites, the liver, and spleen contained but few filariæ, whilst in the bone marrow filariæ were absent. Dr. Manson could not supply any explanation of how these parasites maintain themselves in the arterial blood stream of the carotid or aorta. The facts seemed to point to the existence of some physiological product, the outcome of the activities of waking life, which either drives filaria nocturna from the surface of the body during the day, or attracts it to larger arteries during the night. What this substance may be it is for the physiologist to say.

Section on Laryngology and Otology.

First Day—August 2d.

At the opening of the Section the President, E. Cresswell Baber, reviewed the progress made in laryngology during the past thirty years. He mentioned the important discoveries of Meyer of Copenhagen, who, in 1869, read a paper in London on adenoid vegetations. In 1859, Markusovsky invented the speculum bearing his name. The real advance in anterior rhinoscopy was due more to the use of light reflected from a mirror with a central perforation than to any special form of speculum. The speaker also gave credit to Zuckerkandl for his work on the normal and pathological anatomy of the nose and its sinuses; to Hack for his study of reflex nasal neuroses; to Middledorpf for his invention of the galvanic cautery; to Jellinek for his introduction of cocain into nasal surgery, and to Litchtwitz for his work in chronic empyema. He also spoke of the general recognition of the importance of nasal respiration as one of the fruits of modern rhinology, and said that such progress in the past ought to encourage the workers in this department in their future labor.

Dr. Piéne Lacroix of Paris showed an apparatus for the application of medicated vapors to the upper air tract. Formalin and menthol had yielded him good results in the treatment of tuberculous laryngitis, and he described experiments showing that the vapor inhibited the development of pus cocci and tubercle bacilli.

Dr. Bronner read a paper on

THE USE OF FORMALIN IN ATROPHIC RHINITIS.

He said he stopped short of strengths that caused irritation, using for irrigation a 1 in 1000 or 1 in 2000 solution, though for a coarse spray a rather stronger solution may be employed.

The President, Dr. Snow of Syracuse, U. S. A., and Dr. Pegler described cases in which symptoms of Graves' disease had either supervened upon nasal operations or had been benefited by intranasal treatment.

Dp. Dundas Grant read a paper on

SOME FORMS OF LARYNGITIS CONSEQUENT ON PURULENT AFFECTIONS OF THE NOSE.

He referred to sphenoidal and posterior ethmoidal empyema, and ozena laryngis, describing the macerated aspect and inter-arytenoid swelling, and giving the differential diagnosis from phthisis and syphilis, and the relation to pachyderma.

Dr. Louis Bar of Nice read a paper on

THE DIAGNOSIS OF CHRONIC FRONTAL SINUS EMPYEMA, AND MALIGNANT TUMORS OF THE NASAL FOSSÆ,

emphasizing particularly the impossibility in many cases of ascertaining the cause without exposing the sinus by external operation.

Section on Diseases of Children.

First Day—August 2d.

The President, Mr. Edmond Owen, delivered an address on

UNUNITED FRACTURES IN CHILDHOOD.

He cited a number of authors to prove the frequent occurrence of non union after fracture of the tibia and fibula in children. Operation for this lesion is usually unsuccessful. Non-union in adults is generally due to want of rest, and this may play its part in the non-union of childhood; but the trouble seemed rather to the speaker to be an atrophic one and he suggested that there is some subtle disturbance in the anterior horn of the cord interfering with the nutrition of the bone and rendering it weak and friable and subsequently interfering with its repair. He asked whether any one present had ever established consolidation in the ununited tibia of a child. For his part, he had never succeeded in such an attempt.

Mr. Tubby thought that soft bones are not proper objects for the operations of osteotomy or osteoclasis. He had observed acute fatty degeneration in an old-standing case.

Dr. Maguire opened the discussion on the treatment of pleuritic effusions in children from a medical point of view, including under this heading the operation of simple puncture and aspiration. Treatment was discussed in relation to such questions as the positive tension and resiliency of the thorax, the character and quantity of the fluid, displacement of the heart and abdominal viscera, and the general state of the patient.

Section on Pharmacology and Therapeutics.

First Day—August 2d.

Upon opening the Section, Dr. J. B. Bradbury spoke a few words on the place of pharmacology in the medical curriculum. He regretted very much the growing tendency of most medical schools to require from candidates for diplomas less and less knowledge of the natural history, properties, composition, and action of drugs. While he had no wish to revert to the state of affairs when candidates were expected to have a minute knowledge of the distinctions between the different species of senna, for example, he thought that it is most important that all candidates should be thoroughly acquainted with the different remedies which they are going to prescribe.

A paper on

HEADACHES AND THEIR TREATMENT,

by Dr. T. Lauder Brunton, contained a quantity of interesting information, and brought out the connection of cerebral vasomotor disturbances and toxemia with the majority of headaches not due to local causes.

In the course of the discussion Dr. Dundas Grant pointed out the frequency of nasal troubles as a cause of headache, while Professor Clifford Allbutt was disinclined to attach much importance to vasomotor disturbances. Dr. Harry Campbell dwelt on headaches of syphilitic origin, and recommended the administration of dram doses of iodid of potassium, smaller doses often being insufficient to modify this specific disease. Both he and Dr. J. W. Tyson dwelt on climate as a factor in the production of headaches, while Dr. Herschell referred to over-distention and dilatation of the stomach as frequently associated with headache. On the other hand, Dr. Pope referred to those numerous cases in which headache resulted from an empty stomach. These he attributed to a liver which soon ceases to secrete bile after the taking of a meal. Dr. St. Clair Thomson had often found headache in association with chronic ear disease. Dr. Sarat K. Mullick referred to tropical diseases in connection with headache, and Dr. Masters, speaking from his own experience, agreed with Dr. Brunton as to the vasomotor disturbances present in many forms of headache. The president quoted instances in which smoking had proved beneficial, while Dr. Duffan referred to a variety which he has observed in coal-mine workers.

Dr. Brunton, in replying, mentioned that altitudes and depths probably produced headaches by altering the atmospheric pressure in the sinuses.

REVIEWS.

Injuries and Surgical Diseases of the Face, Mouth and Jaw. By John Sayre Marshall, M.D., Former Professor of Dental Pathology and Oral Surgery, and Emeritus Professor of Oral Surgery, in the Dental Department of Northwestern University. Philadelphia: The S. S. White Co.

The author's plea for the creation of this work is that no text-book on this collateral branch of surgery is adapted to the recitation system of teaching. To attain this end the volume has been so written that each chapter ends with a number of questions reviewing the topics discussed therein. One must regret the introduction of such a plan into a text-book whose dignity cannot but be impaired thereby. Such elementary methods had best be reserved for quiz-compends.

In substance the ground is well covered, yet by being more exclusive the representative features, reflecting the author's individual experience, would not be so obscured, and the authoritative remarks would have come to the fore. Aside from the excellent illustrations there is nothing distinctively meritorious in the work to commend it to physicians who have numerous books on general surgery admirably covering the same ground; this volume, however, is deserving of a hearty welcome by students of dentistry, for whom it seems to be intended.

A System of Medicine. By many writers. Edited by Thomas Clifford Allbutt, M.D., LL.D., Regius Professor of Physic in the University of Cambridge. Volume VI. New York: The Macmillan Company, 1899.

The sixth volume of Allbutt's system of medicine deals with the diseases of the circulatory and nervous systems, the former being continued from the previous volume. Among the contributors is Dr. William H. Welch, who has written two scholarly articles on thrombosis and embolism. The diseases of the muscles are considered in four chapters under the heads of myositis, myotonia congenita, idiopathic atrophy, hypertrophy and facial hemiatrophy, and hemihypertrophy. Dr. Bevan Lewis opens the series of articles on the nervous system in a consideration of its general pathology. The trophoneuroses are next discussed, then the diseases of the nerves, and finally the diseases of the spine.

This volume of the system does not differ from its predecessors in its general excellence. The value of the work is, indeed, enhanced by some of the monographs contained in the book under discussion. We are not acquainted with any system its superior in scientific or literary excellence.

Transactions of the American Dermatological Association. Twenty-second Annual Meeting, held in Princeton, N. J., May 31 and June 1, and in New York City, June 2, 1898. Concord, N. H.: The Rumford Press, 1899.

Those interested in diseases of the skin will find many valuable papers in the *Transactions* of 1898. To review the important papers in detail would mean to review nearly all of those read. A valuable contribution is the one by Gilchrist on the question of malignant growths arising from pigmented moles. These are usually regarded as sarcomatous in nature, but Gilchrist agrees with Unna, who was the first to oppose this view in 1892, that they arise from the rete layer of the epidermis and not from endothelial or connective-tissue cells, and hence should be classed with the carcinomata. Some excellent drawings by the author show the histologic features very clearly and seem to confirm this view.

Text-book of Ophthalmology. By Dr. Ernst Fuchs, Professor of Ophthalmology in the University of Vienna. Authorized Translation. Revised from the Seventh German edition. By A. Duane, M.D., Assistant-surgeon in the Ophthalmic and Aural Institute, New York. Illustrated. Second American edition. New York: D. Appleton & Co., 1899.

Since the first edition of this book was published five German editions have been issued, and Fuch's work is accepted as the model ophthalmological text-book in matter as well as in presentation. The data are selected and presented with such judgment and care, the information is so complete and fresh, the scientific analysis so precise that the most abstruse chapters are simplified and made intelligible. Much of the pleasure derived from reading this book depends upon the fact that the author has everywhere substituted the results of experience, mainly personal, for the customary theoretical deductions or traditions, while the whole subject matter is illustrated by a style which is as graceful as it is clear and simple. In this regard the English version is fully worthy of the original, and the translator is to be congratulated on the felicitous manner in which he has accomplished his task.

The second American edition represents an essentially improved form of work which has already proved valuable. It bears everywhere the marks of thorough revision, of additions, and corrections, notably in the sections on functional examination, the pathology of corneal and conjunctival diseases (especially the parts relating to ulcus serpens and diphtheria), and the diseases of the fundus. The translator has added a short chapter on the subject of heterophoria, judging that the presentation by Professor Fuchs, while admirable in point of matter and lucidity, might appear too brief to many readers in this country, where so much attention is given to muscular anomalies. Another section inserted deals with the use of homatropin and other cycloplegics, and the general subject of the correction of refractive errors. The book is thoroughly abreast of the times, and presents an excellent summary of ophthalmological science as we know it to-day.

Regulations for the Guidance of Surgeons in the Medical Examination of Recruits for the Connecticut National Guard. Middletown, Conn.: Pelton & King, 1899.

This little volume has been prepared by Brigadier-General J. Francis Calef, Surgeon-General, C. N. G. It con

tains besides general instructions to examining surgeons, an enumeration of the conditions exempting from military duty and of disqualifications for service in regular and in State regiments. Test-types for determining the vision of recruits accompany the volume, and the text of the Geneva Convention is appended.

HAY-FEVER AND ITS SUCCESSFUL TREATMENT. By W. C. HOLLOPETER, A.M., M.D., Clinical Professor of Pediatrics in the Medico-Chirurgical College of Philadelphia. Second edition. Philadelphia: P. Blakiston's Sons & Co., 1899.

THE call for a second edition of this little monograph within a year is evidence of the widespread interest taken in the subject-matter, as well as of the practical excellence of the work itself. The thorough clinical study of hay-fever, and the exhaustive review of the literature devoted to it, are again presented, while the author has revised and enlarged the text so as to include the special treatment of each of the various types of hay-fever cases. The bibliographic section is made to include the most recent publications, and the work is a complete presentment of a most important topic.

LABORATORY WORK IN BACTERIOLOGY. By FREDERICK G. NOVY, SC.D., M.D., Junior Professor of Hygiene and Physiological Chemistry in the University of Michigan. Second edition. Revised and enlarged. Ann Arbor: George Wahr, 1899.

THIS work is not offered as a complete text-book of bacteriology, still it contains a vast amount of important matter on the subject, and is admirably arranged as a working guide for the student. The present edition is a work of nearly 600 pages, divided into fifteen chapters, and contains many illustrations, most of which deal with the apparatus necessary in laboratory technic. Illustration of the growth and appearances of the various bacteria have been omitted purposely, and the book is interleaved with blank pages, so that the student may draw what he observes.

We note with particular satisfaction that great care has been given to those minute details in technic that are so important to every beginner, and that are so frequently missing in the ordinary books on the subject, and can heartily commend the work as a safe guide to all students interested in this important science.

THE TREATMENT OF DISEASE BY PHYSICAL METHODS. By THOMAS STRETCH DOWSE, M.D., Abd., F.R.C.P., Edin., formerly Physician-Superintendent Central London Sick Asylum; President North London Medical Society. New York: E. B. Treat & Co., 1899.

UNDER this title the author presents, in unchanged form, his "Lectures on Massage and Electricity in the Treatment of Disease." As under the old name the work is devoted for the most part to a discussion of the theoretical aspects and practical application of massage. Each chapter corresponds to a lecture—the first elucidating the mechanical principles of massage and their chemico-physiological relations; the succeeding lectures dealing with the various kinds of massage and their administration to the different parts of the body (freely illustrated). A rather original lecture is devoted to the Weir Mitchell "rest cure." The last three chapters deal, respectively, with "The Schott Treatment in Diseases of the Heart," "Electro-Physics," and "Electro-Therapeutics."

The writer has imparted a distinct clinical interest to his lectures by keeping before the reader's mind the interdependence of physical and other therapeutic measures in the successful treatment of various diseases. He dwells with emphasis on the importance of adopting the physical treatment to the condition of the patient.

THERAPEUTIC HINTS.

To Prevent Loosening of Teeth.—When it is desirable to counteract a tendency to this condition the following mouth wash is recommended:

℞	Ac. tannici	ʒ ii
	Tinct. iodi	ʒ i
	Potassii iodidi	gr. xv
	Tinct. myrrhæ	*m.* lxxx
	Aq. rosæ	℥ vi.

M. Sig. A teaspoonful in water to rinse mouth every two hours.

For Seasickness.—

℞	Cocainæ hydrochlorat.	aa	gr. i
	Ext. opii		
	Pulv. altheæ		q.s.

M. Ft. pil. No. VI. Sig. One pill every two hours.—*Eid.*

For Hemicrania.—

℞	Antipyrin	aa	gr. xlv.
	Sodii bicarb.		

M. Div. in pulv. No. VI. Sig. One powder every half hour (from 2 to 4 doses a day).

Or the following:

℞	Antipyrin		gr. xlv
	Caffeinæ citrat.		gr. x
	Sparteini sulphat.		gr. ii.

M. Div. in pulv. No. VI. Sig. As above.

At night the following pill is taken:

℞	Ext. belladonnæ	aa	gr. i.
	Pulv. belladonnæ		
	Resinæ podophylli		

M. Ft. pil. No. VI. Sig. One pill at night.—*Grasset.*

For Scabies.—

℞	Sulphuris precip.	aa	℥ ss
	Bals. Peruviani		
	Resorcini	aa	gr. xxiv
	Ac. salicylici		
	Vaselini	aa	ʒ i ℥ vi.
	Lanolini		

M. Ft. unguentum. Sig. External use.—*Besnier.*

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, AUGUST 26, 1899. NO. 9.

ORIGINAL ARTICLES.

CERTAIN CLINICAL OBSERVATIONS UPON HEART DISEASE.[1]

BY EDWARD G. JANEWAY, M.D.,
OF NEW YORK.

IN thinking over subjects upon which to make a short address to you I could think of none which might prove of more interest than certain clinical observations upon heart disease, presenting the subjects to you as they have occurred to me. In the time allotted I shall be able only to touch upon the disappearance of the murmurs of mitral insufficiency, certain phases of mitral stenosis, and endocardial fever.

In my earlier medical life I was rather incredulous, when the statement was made to one with heart disease, which from all methods of reasoning was a mitral insufficiency dependent upon organic cause, that he might outgrow it. My former friend and colleague, the late Professor Austin Flint, would not infrequently cheer despondent patients with such a hopeful outlook. Hence I have taken especial interest in certain cases of this nature which have fallen under my own observation. Of course you are all familiar with the appearance and disappearance of a systolic mitral murmur during and following some severe illness, where such murmur may be taken to have indicated an insufficiency due to muscular weakness occasioned by the illness, and the disappearance to the improvement of the strength of the heart muscle preventing the previous leakage. Whether such explanation can be made to apply to the following cases I leave to you:

A young lady, aged thirteen years, had a well-marked murmur characteristic of mitral insufficiency, audible at the apex, plainly heard over the posterior part of the left chest, and nearly as much so on the right side. The history given to me at the time was that she had suffered from inflammatory rheumatism when much younger and that the heart disease had then developed. Under my observation she had only a moderate enlargement; there was no marked hypertrophy of the right ventricle. At times she would suffer from palpitation, and she was unable to stand much fatigue. From time to time she had slight attacks of subacute rheumatism. Only at intervals did her heart need regulation by digitalis. Reasonable counsel was given as to the mode of life she should lead, such as would prevent increase of the condition by forced exertion, over-fatigue or undue excitement. For eighteen years as I from time to time examined this young woman the murmur continued audible. But for two years past I have been unable to hear it except upon one occasion after a rather severe attack of influenza and then only for a couple of days.

In this instance a murmur characteristic of mitral insufficiency present for eighteen years under my own observation, and for several years prior to that under the observation of another physician, originating from an attack of rheumatism, has practically disappeared. We are obliged to ask What has produced this change? Two explanations more particularly can be offered. The first would claim that during all these years there had only been a persistence of such a state as exists in the insufficiency of weakness following disease, and that at no time had there been any distinct thickening or shortening of the mitral valves. The most admitted under this theory would be perhaps some dilatation of the left ventricle and especially of the mitral ring. It would also be claimed that as she became older the muscle force increased, and the base of attachment became firmer thus diminishing the size of the orifice and finally allowing the valves to so close as to prevent leakage. Under another explanation it might be supposed that the thickening of the valves was not great, the shortening hence trivial, and that the valve segments may have become united to such an extent as to prevent leakage, but not to so considerable a degree as to cause the evidence of mitral stenosis. Such an explanation occurred to my mind and induced me to endeavor to make out such a mitral presystolic murmur. But listen as I would I could not thoroughly satisfy myself as to its presence. This murmur, it may be stated, did not disappear because of heart weakness, for the patient since the murmur has been lost has been in better health than heretofore, and some of the previous restrictions have been withdrawn.

The other illustration also occurred in a girl, eight years of age at the time of the inception of her trouble. She at first had rheumatism, which was followed by mitral insufficiency. Later she had an attack of chorea and again subacute rheumatism.

[1] Read at the Centennial Celebration of the Medical and Chirurgical Faculty of Maryland, Baltimore, April 27, 1899.

The murmur as in the preceding case was audible over the back as well as on the front of the chest. From time to time as she was examined the murmur continued present until she had reached the age of eighteen. I had not seen her for more than a year, and was surprised at my inability to detect the previously present murmur. She stated that she felt well and was not now inconvenienced by her heart. I examined her subsequently with a similar result. Such commentary as I have made of the first patient will suffice for this.

In a third patient, also a young woman, who had a murmur of mitral insufficiency but not so well marked, nor so loud as the two above noted, death came about from an entirely different cause. At the autopsy made by a pathologist unaware of the previous history the report was that the heart was normal—unfortunately the hydrostatic test was not used, nor was the width of the mitral orifice noted. This young woman had the heart murmur develop as a sequel of rheumatism. The late Professor Flint had given her the assurance which I have above noted. I had examined her from time to time for several years always finding a mitral systolic murmur audible posteriously though when quiet in bed at the beginning of her serious sickness an examination did not disclose it. After this I did not see her, and only have the post-mortem record upon which to form a theory. It certainly points to the possibility of the continuance of a mitral leakage after rheumatism for years without the presence of organic change in the valves.

The speaker while upon this subject feels inclined to draw your attention to the disappearance of the murmur of mitral insufficiency in the course of Graves' disease (exophthalmic goiter). My inclination at one time was to suppose, in this disease, with a rather enlarged heart and a plainly audible murmur of this character, readily heard posteriorly unless the murmur disappeared fairly rapidly under treatment, that it would be a permanent affair. Whilst several cases of the disappearance of the murmur in this disease have come under my observation two only are possessed of sufficient interest to warrant a short outline of their history. The first occurred in a lawyer of thirty-five, who had come from the South to consult me. At home his disease had been considered severe neurasthenia. On his way to New York he had stopped at a medical college where the professor of medicine had informed him that he had incurable heart disease. Pending my arrival from a trip out of town he had consulted a neurologist, who had given him a diagnosis of embolism of the spinal cord. His condition was one of great weakness. He had marked tremor. The pulse was from 140 to 160 per minute. There was moderate exophthalmos, and the Von Graeffe symptom was well marked. The thyroid was fairly enlarged and the thrill and murmurs so characteristic were readily felt and heard over the arteries of the neck and over the thyroid. The heart was enlarged, somewhat weak, and beat as rapidly as the pulse indicated. He was weak and troubled with diarrhea. There existed a mitral insufficiency murmur plainly audible on the back of the chest. As occurs at times in Graves' disease, he would occasionally fall down while walking. The existence of an enlarged heart with a mitral systolic murmur had caused the diagnosis of incurable heart disease. The falling to the floor while walking, in a person with a loud heart murmur, had caused the diagnosis of embolism of the spinal cord and a correspondingly bad prognosis.

This patient made a complete recovery in the course of three months—under the use of iron, strophanthus, improvement of nutrition, the cure of the diarrhea, and the application of rest. He was much helped by the assurance of recovery. The mitral insufficiency murmur entirely disappeared.

The second patient was a lady of about forty years. Her disease had been due to or rather followed an accident. While traveling in a mountainous country the donkey on which she was riding slipped on the edge of a precipice, and she was saved by catching on a tree which grew below the level of the edge. The occasion of my seeing her was that a physician in attendance had told herself and her husband that she had incurable heart disease. When I first examined her she had moderate exophthalmos, an enlarged thyroid, and marked thrill and murmur over the arteries of the neck and thyroid. Her pulse was 120 to 130 per minute. The heart was somewhat enlarged by palpation and percussion, and a marked mitral systolic murmur was audible at the apex conveyed behind and heard on both sides posteriorly. She had lost weight. There was a fully marked tremor and a sense of heat. The Von Graeffe symptom was also present. Later edema of both limbs developed. I had told her husband that I thought she could be cured and that we should regard the heart murmur as due to muscular weakness if it should disappear within three months. This lady in the end made a complete recovery except as regards the exophthalmos, of which there was still some trace when I last saw her. The murmur, however, did not disappear for more than nine months, and when the edema of the legs developed I feared that I had been a bad prophet. The treatment which brought about recovery was assurance that she had a disease from

which she could get well, and not incurable cardiac disease, the use of strophanthus, iron, and when edema occurred the addition of digitalis to the strophanthus. Galvanism to the neck was also employed. The attempt was made to improve the nutrition. Two years after her recovery I examined her when she had come in from a walk of over a mile and it was impossible to hear any evidence of mitral leakage. Allow me to say in passing that my experience with Graves' disease in private practice has been that the patients recover. In hospital experience, on the other hand, the results have not been as good This I ascribe in considerable degree to two facts: first, a large hospital with its attendant scenes and incidents is a poor place for this class of patients; and second, to the apparent impossibility of pursuing the same continued plan of treatment on a moderate basis.

Certain observations with mitral stenosis have also sufficiently interested me to place them before you. It is as you know very generally claimed that the mitral presystolic murmur is only audible over a limited area at or near the apex. In about one third of the cases of this type of disease I think that one would be able to make a probable diagnosis by listening at the back of the chest below the angle of the scapula where in this proportion of cases a murmur can be heard, not so loud, nor so plain, it is true, as in front. This, of course, is in opposition to the generally received view, and is opposed to the teaching of many of the text-books on physical diagnosis. I feel assured that with a careful study of the facts of the case you will agree with me. No form of heart disease is more often overlooked than mitral stenosis, in which there exists only a slight presystolic murmur, and I am convinced that teachers of medicine should give more time to having students acquire the faculty of making the diagnosis of this type I have had four cases of this disease in which the first evidence of cardiac impairment was brought about by exercise at high altitudes. The first concerned a gentleman who had gone into a mine at Leadville (11,000 feet) and on coming to the surface suddenly lost the sight of one eye. On his return he consulted me with relation to this, which was found dependent upon embolism of the central artery of the retina. This had come from a heart of which the only lesion was mitral stenosis and its effects. From this time on he had gradually progressing cardiac impairment. The second concerns a lady, at that time living at Telluride (9000 feet) who brought her daughter to me suffering with chorea, and incidentally asked why she felt so bad when going up stairs at home. She had mitral stenosis of the type indicated, and was ignorant of the existence of heart disease, though she had consulted a number of physicians. Later I learned that she had been forced to seek a lower level, and was affected with cerebral embolism, aphasia, and hemiplegia. The third concerned a lady, who informed me that she had run at an elevation of 10,000 feet in the Himalayas. Previously she had been unaware of any heart trouble, but since she had suffered more or less from cardiac impairment. The fourth recently told me that she had run with a rifle in her hand several hundred feet at an elevation of 7000 feet in Yellowstone Park, when she dropped from inability to proceed and from cardiac distress. Since this time she had had more or less cardiac disturbance. Her heart exhibited the murmur mentioned. She consulted me for headaches, and not for the heart trouble, though in obtaining her history I found that she was unable to do much which had been formerly possible.

Again I have known several patients who have been examined on account of severe illnesses, in whom I have detected the murmur of mitral stenosis. In some of these on obtaining the history I found that where formerly they had suffered with what were considered asthmatic attacks, after taking to the bicycle there had been a marked improvement in their condition.

Another consideration worthy of a passing notice is the substitution of the mitral systolic murmur for the presystolic as the heart compensation is markedly disturbed. My attention was drawn to this years ago when teaching. A patient whom I had shown one year as a well marked illustration of mitral stenosis with a plain presystolic murmur, after being out at hard work would return with edematous legs, congested liver, etc., and be sent to me as a case illustrating mitral insufficiency and I would be forced myself to admit the change of the murmur. After rest and treatment very probably the old order of things would be reproduced. The systolic would give place to the presystolic, or the diastolic and presystolic. In the case of one patient this occurred three times. It is in part owing to the non recognition of this by some that part of the confusion with reference to the diagnosis of mitral stenosis has been produced. Well-marked mitral stenosis would be found at an autopsy in a person whose disease from the heart murmur had been considered mitral regurgitation. This occurs more especially in hospital practice and in patients coming in with much broken compensation. These have not, of course, been under observation by the same physicians previously.

Your president, Professor Osler, has done so much by his investigation and writing to inform the medical profession about malignant endocarditis that in

touching upon this as a third topic I feel much as he who brings coals to Newcastle. Still I trust that it will not burden you, if from a considerable experience I draw your attention to certain phases which have interested me. The disease is so protean in its manifestations, so different a clinical picture is presented by the sufferer with the acute variety compared with that presented by the victim of the chronic type, and the diseases with which mistakes in diagnosis are likely to be made are so divergent, that the question has forced itself upon my mind whether the employment of the term endocardial fever might not be of service. Owing to the number of manifestations which the disease presents we are in need of a number of subdivisions, if we wish to make the best use of the memory of our previous cases. It has also seemed to me that physicians with whom I have seen cases have not had their attention drawn to the possibility of the existence of the disease in such cases as were of the mild chronic type, when the terms ulcerative, infectious, malignant were employed. If among the fevers we could introduce the term endocardial, then the student would hold in mind the possibility that in any given case he must consider this as a possible position for the origin of fever. I must confess that the objection can be urged against its employment that we might as well speak of pleural, cerebral, and other fevers, as to consider the place instead of the process in designating a fever. However that may be I must confess that in not a few cases of the chronic type I have derived satisfaction from the use of the term. From such experience as I have had with the disea e I would be inclined to make two separate divisions. The first would be according to the type—peracute, acute, subacute and chronic. The other would aim to present the different ways in which the disease may occur.

1. With heart murmur: (*a*) Hemorrhagic, (*b*) with embolism, (*c*) with or without hemorrhages, and febrile.

2. Without heart murmur: Still again according to the type of the fever we could very well make a classification with continued fever, with remittent fever, with intermittent fever, with chronic mild hectic fever.

Again it would not be difficult to construct a class as primary and secondary, using this designation even in a double sense, so as to include cases in which the inflammation affected a heart whose endocardium was previously healthy, and that which was previously diseased, or, on the other hand, to signify that the endocarditis was the primary lesion and such events as happened were dependent upon its affection, or that the inflammation of the endocardium was only part of a process whose origin was in a septic focus within the system.

Formerly I encountered a comparatively larger number of the acute cases, and my introduction to the case was more particularly to decide whether the person was affected with some infectious disease, and to give it, if possible, a name. I have thought it possibly profitable to present this part of the subject to you as I have been forced to consider it. The most frequent inquiry is, so far as the acute malignant type is concerned, whether the patient has possibly any of the malignant types of the ordinary infectious diseases. Especially may the mistake be made between purpura variolosa, cerebrospinal meningitis, and typhus fever. Only in the large seaboard cities is the last fever likely to be considered. In trying to determine whether a given case is more probably due to endocarditis or to another malignant process I have found that attention to the position of the hemorrhages is at times very helpful. Several times I have noted numerous small hemorrhages with slight nodular character in the palms of the hands and in the soles of the feet, when possibly the arms and the legs had but a scanty crop in malignant endocarditis, whereas this has not been my experience with the processes likely to be mistaken for it. The presence of hemorrhages in the conjunctiva is also more in favor of this disease, particularly if the inquiry be between it and typhus fever. While the presence of a heart murmur, together with the above events, suggests strongly ulcerative or malignant endocarditis, it is well not to argue thus without a definite basis. There exists no reason why a person with heart disease should not develop one of the malignant types of fevers. If a patient be in a hospital-ward, hotel, or boarding-house then we are compelled to endeavor to solve the question at as early a period as possible with a view to the patient's isolation or removal if he should have another process than endocarditis. Hence we are obliged not alone to consider the probable diagnosis as made from the events, but also to institute an inquiry as to previous vaccination, and possible exposure to some disease within a recent period. There are certain phenomena in a doubtful case which have great weight as the occurrence of embolic processes, as proven by the development of hemiplegia, aphasia, or by the proof of the blocking of an artery of the limbs. These phenomena would not occur in the other types of disease. A heart murmur, if none were known to have previously existed, or if the one previously present has altered in character, taken in conjunction with these phenomena, make the diagnosis of malignant endocarditis as near a certainty as anything in medicine.

A brief sketch of two cases will bring this out in its proper light. One evening, after having spoken upon the subject somewhat dogmatically, a physician asked me to see a case with him which he feared was possibly malignant typhus or variola. The man had been employed as floor-walker in a large department-store, he lived in a boarding-house, and it was desired at as early a date as possible to name his disease. He had previously suffered from rheumatism and had well developed heart murmurs. On inquiry the physician stated that these had altered in quality. In the poor light it was only possible to make out the distribution of the larger extravasations. There existed a very profuse, reddish eruption on the palms of the hands and the soles of the feet which was slightly nodular. The man was semicomatose. The conjunctivæ, neck, and body showed hemorrhages, but the skin of the legs and forearms were almost free. He had a mark of vaccination. No variola was prevailing in the city. He had only been ill for three days and had high fever. Typhus fever had never presented itself in this aspect and these points seemed to justify the exclusion of variola, hence a diagnosis of ulcerative endocarditis was made. In this instance the appearance in the daylight was far better for diagnosis than that at night. The autopsy made a day later showed the disease to have been attended by as profuse internal hemorrhages and embolic processes as on the exterior. A careful questioning failed to prove the point of entrance of the germs productive of the disease.

The second case occurred in a young lady who had chronic valvular disease, the result of rheumatism. She had a week previously suffered from a profuse epistaxis, which had required plugging of the nares for its arrest. The plug had been allowed to remain several days. The young lady's family were not alarmed at her condition until the day of my visit. She had complained of pains and fever, and now had become somnolent. When seen, she lay in a dark middle room, was comatose without stertor, had a loud mitral murmur, altered in character, according to her physician, with a rectal temperature of 106° F., and a pulse of 130. I was unable to make out positively the diagnosis of ulcerative endocarditis because it was impossible to determine in the light at hand the presence of petechiæ. Seen the next morning she presented these abundantly over the body, neck, face, and on the conjunctivæ, her coma had deepened, and the rectal temperature was 107° F. She died on the evening of the second day after the serious symptoms developed. In this case I think we may justly claim that the place of entry of the germs was from the nasal mucous membrane.

The most difficult of the acute cases to recognize are those in which no heart murmur exists, or where the lesion is on the right side, and the secondary effects are in the lungs more especially. In the former we are apt to be thrown off our guard; yet by paying attention to the previous noted study of petechiæ, especially if combined with irregular nervous phenomena, we may make a correct diagnosis. In the latter the danger is of mistaking the pulmonary lesion for primary. Yet it must require a very close analysis to determine whether the pulmonary phenomena antedate the cardiac lesion, or, on the other hand, the endocarditis is the result of pneumonia, as may happen.

Acute yellow atrophy of the liver was supposed to exist in one case though there was only the fever, petechial eruption, and the typhoid state, delirium, and unconsciousness to suggest it, while in favor of the ulcerative endocarditis were the normal size of the liver, not diminishing under observation, and a plainly distinguished heart murmur. The jaundice was found to be associated with an embolus in the hepatic artery. At times it has been extremely difficult to establish a diagnosis of endocarditis as opposed to a continued fever. This will happen especially in hospitals where patients are admitted in the middle course of the disease, who have a slight murmur at the mitral, about whose past history there is no knowledge as regards the previous presence or absence of such murmur. With the newer means of examination fewer errors of this kind are likely to happen, for with the Widal test, the culture of the feces, and a leucocyte count we will, if chance be given for continued study, arrive at the approximate truth. But it is an interesting question whether certain of the cases in literature quoted as establishing the succeedence of malignant endocarditis to variola, typhoid fever, etc., may not have been dependent upon the post-mortem findings, added, whether rightly or not, to the ante mortem diagnosis. More chances of mistake for malaria exist in my experience in two types. The first includes those cases in which a chill, fever, and sweat occur with tolerable regularity, yet neither plasmodia can be found in the blood, nor does the disease yield to quinin. I had a very marked example of this type coming to my office for a number of days. The periodicity was well-marked, the temperature on several occasions reaching 104° to 105° F. in the office. Daily examinations failed to show plasmodia, a leucocytosis was present, and quinin in different forms failed to relieve. Finally the patient developed a pulmonic systolic, and later a pulmonic insufficiency murmur. In this person there had been a gonorrhea when, ten weeks prior to other symptoms

certain joint pains occurred, followed by this intermittent fever. With the development of the heart murmur I felt that it was wrong to have him take a long trip daily to my office and advised him to enter a hospital. He was admitted to St. Luke's, where, after a serious illness, fever, pulmonary complications, and nephritis, he made a recovery. He is the only illustration of this termination in cases in which I have felt forced to a diagnosis of malignant endocarditis. I have also met one case long considered and treated for intermittent fever in a hospital prior to the days of plasmodial examinations in which the autopsy showed ulcerative endarteritis with vegetations on the first portion of the aorta.

The form which more commonly leads to the diagnosis of malaria is the chronic type, where for weeks and months the only phenomena are daily fever and gradual exhaustion. At times embolism occurs so that help is given in establishing the diagnosis by that event. The failure of quinin to produce a cure soon leads to a change of opinion and either tuberculosis or sepsis from some hidden abscess is considered the cause of the sickness. In all cases of this kind where a heart murmur exists endocarditis should be considered as the probable cause of the fever unless definite trouble can be found elsewhere. I have two cases at the present time, one of which has lasted over a year and the other for five months, where search as I may no proof of other cause for a fever can be found than to consider it endocardial. We can, of course, in some cases be helped not alone by the blood-count but also by the blood-culture, providing it is carefully performed. Formerly with simple skin pricks the chances of mistake were too great. Yet when we have obtained a positive result will it materially aid our therapeutics? It has been difficult to have the serum used, and yet in the two cases where I recommended its employment in endocarditis no positive good result followed. I have tried varied remedies without avail and have of late, in despair at the hopelessness of the picture, determined to obtain the germ from the blood, and apply serum-therapy accordingly when possible. My present position is but one patient recovered and that followed gonorrhea.

The disease seems to me to be on the increase, for within the past year eight cases have been observed either of the subacute or chronic type. In two cases gonorrhea was the probable cause, but in the remainder it was not possible to locate or name the point of departure of the disease. I questioned the people, their physicians and friends in vain.

A few words might have been devoted to the discrimination from tuberculosis but the rules are sufficiently known. The chronic cases are in my experience very generally considered to be tubercular though in the absence of physical signs the pendulum swings usually from malaria to tuberculosis.

THE CLASS METHOD OF GYMNASTIC TREATMENT OF LATERAL CURVATURE OF THE SPINE.[1]

By WALTER TRUSLOW, M.D.,
of Brooklyn, N. Y.;
Assistant to the Chair of Orthopedic Surgery in the Long Island College Hospital; Clinical Assistant in the New York Hospital for Ruptured and Crippled, and in the Brooklyn Hospital.

This paper is a review of the work and results obtained in the lateral-curvature clinic at the New York Hospital for Ruptured and Crippled during the last year and a half. I shall hope to show that, although the individual application of exercise, whether heavy or light, is more accurate and effective than group work, the latter is not only a valuable aid in bettering the condition of even the worst cases of scoliosis, but may alone cure the milder forms.

The surgeon's aim in the treatment of lateral curvature should be the development of the patient's physique to as high a degree of efficiency as possible. Believing that the employment of such measures as increase the functional activity of the entire motor apparatus—nerve mechanism and muscular mechanism—is the most rational and scientific procedure in the majority of cases, the problem on undertaking the dispensary work was how to apply the exercise treatment to the many patients presenting widely varying conditions.

The symptom of pain is found in comparatively few cases. But in some it is very real and intense, and seems to be of two varieties, etiologically considered: The rheumatoid pain, found more frequently in early cases with purely postural deformity, and due to the continual dragging on poorly nourished and poorly developed muscles; and the neuralgic type, more apt to be found in old fixed cases, and caused by pressure on the intercostal nerves by the infolded and retracted ribs of the concave side. Relief is sought and should be given in either case. A carefully fitted and applied Knight or other brace, or plaster-of Paris jacket, will accomplish this in most cases; but the best are burdensome and hamper the motions of the body; in a word, they limit the actions of the working apparatus. But the majority of patients, whether in private or dispensary practice, do not come to the orthopedist because of pain. "Her shoulder is getting higher," "the hip is growing out," "her dress don't fit her well," "she stands and sits so

[1] Read at the Thirteenth Annual Meeting of the American Orthopedic Association, held at New York, May 31, June 1 and 2, 1899.

crooked"—there is a recognized asymmetry, and the surgeon is asked to remove it. Dypsnea and cardiac embarrassment may be present in late cases and require careful treatment.

The record of the seventeen months ending May 1, 1899, shows 199 cases examined. The ages of the patients have varied from four and one half to twenty-four years, the greatest number being from eleven to sixteen years old. Ninety-three per cent. were girls. Four were colored. Under hereditary conditions it was noted that in 15 cases a similar deformity had been present in one or more near relatives; in 8, some tubercular history; in 5, cardiac, and in 3 nervous system complications were present in the family, and one was a twin, the sister being much stronger than the patient presented. An early history of measles was recorded in 126 cases, of scarlet fever in 48, and of diphtheria in 43. Other forms of previous disease were pneumonia, 7; empyema, 3; paralysis, 3; chorea, 17; meningitis, 3, and rickets, 10—although evidences of the last disorder were found to exist in a far greater number of cases. The occupation varied with the age. Thus, the great majority—141 out of 199—were at school about six hours every day; 9 were factory employees; 6 held clerical positions; 6 were dressmakers; 3 domestics; 2 children's nurses; 1 cooper; 1 devoting his time to violin study, and 30 living at home with no very definite occupation—all leading more or less sedentary lives. Indeed, with but few exceptions, it was found that they were, and had been for some years, less active than those about them. They did not enjoy exercise, and often they were distinctly discouraged in it by their parents.

At the time of the onset of the deformity the increase in height had been so marked in thirty-five cases as to lead to the belief that a rapid increase of bone lengths without a corresponding increase of girth measurements—comparative muscle atrophy, if I may so say—was in itself a not infrequent cause of curvature. Certain habits of posture were carefully looked into, and it was found that (1) the carrying of heavy weights, books, or a baby brother or sister on one side more than the other; (2) the unequal distribution of the weight of the body while standing; and (3) asymmetrical positions at desk or other work, one or all of them, were either observed or easily elicited in the great majority of cases. There was a great inability on the part of parents in any way to account for the conditions found. This is to be explained by their ignorance and lack of observance of their children. But a fall or other injury to one side of the body was traceable in twelve cases and astigmatism in two. The effect of an injury in initiating a curvature I would explain by the profound impression made on the child in the necessity to limit movement on that side, partly conscious at first, and afterwards becoming habitual. Unequal vision, a well recognized cause of curvature, I believe, to exist in many more cases than those noted. Certain less common, but easily traceable causes, were recorded. These included, actual difference of more than half an inch in length of lower extremities, in 8; marked contraction of one side of the chest from excision of one or more ribs, 3; torticollis, 2; partially ankylosed elbow-joint in semiflexed position from contracting cicatrix, 1; unilateral spastic contraction of pectoralis major, 1; old dislocation of shoulder-joint, 1; talipes varus in girl of fifteen, 1.

Decided difficulty was experienced in ascertaining the time of onset, hence the duration of the deformity. Previous treatment had been given in 168 cases, and included corsets with the purpose of "straightening her," in 135 patients; a special brace, 16; plaster of Paris jacket, 3; electricity, 1; and some form of gymnastics, 13.

The general examination of the patients showed headaches to be present in 7 cases, localized pain in 39, marked dyspnea in 1, leucorrhea in 5, dysmenorrhea in 4, general rheumatism in 1; also a decided heart lesion in 9, anemia in 9, and mental deficiency in 3.

The forms of curvature were classified as follows: Posterior curvature only, *i. e.*, round shoulders, abducted scapulæ, etc., 35; posterior curvature most marked, but with some lateral deviation, 17; single lateral curve to the right, 7; single lateral curve to the left, 21. *Compound. Right dorsal, left lumbar:* First degree, purely postural, no rotation, 32; second degree, rotation present, 58; third degree, rotation fixed, 22; total, 112. *Compound. Left dorsal, right lumbar:* First degree, postural and no rotation, 1; second degree, rotation present, 4; third degree, rotation fixed, 2; total, 7.

That is to say, that of 199 patients examined, a little less than half had postural asymmetries, or those which they could by will power or by suggestion entirely overcome, and a little more than half were afflicted with deformities more or less fixed and beyond the control of their motor apparatus.

The treatment followed has aimed through class work almost exclusively for the first type just mentioned, and through class work supplemented by frequent individual suggestion and exercises in the second type, so to increase the size of the muscles and train the motor apparatus, that they will retain or more easily approximate the ideal position.

Patients presented themselves at all times of the year, although it was observed that there was an in-

crease of school children during the early months of the fall, and an increase during the spring of the older working people. This stringing along of the patients, and the fact that no one so far has been refused treatment were practical difficulties in the class method, which it is proposed to obviate in the future by starting a new class every two months and commencing only individual work at once, where that is thought desirable. This would include an extra physical examination of all under treatment just before the new class commenced to determine (1) who should be discharged as cured; (2) who should be advanced to a class having more difficult work; (3) who should remain where they are, and (4) who, having had a fair trial of perhaps a number of months without improvement, should be dismissed as worthy subjects of a charitable institution whose function is to treat chronic patients —clearly, not the purpose of an out-door dispensary. The question might be asked, Why receive these cases at all if they are incurable—why not dismiss them at first? The answer is that it is impossible to tell results at the time of examination; that many of the worst and apparently most hopeless cases have, through their determination and perseverance, made most marked improvement; while others, with but little deformity, but more listless, and handicapped by poor hygienic and dietary surroundings, have shown but little improvement, and in a very few cases have seemed to become worse.

Treatment is given three afternoons a week, from two until five o'clock, in a large room especially set apart for that purpose. There are now four able assistants, young women who are graduates of leading normal schools of gymnastics in the country, who help, two in the class work and two in the individual work exclusively. After examination and shadowgraph record of the case, the patient is assigned to the proper class and also to his day of special work, if it is necessary to add this. He is instructed to procure a cheap form of gymnasium slippers, and to have loose clothing for the exercise. For the girls, and especially those who are wearing long dresses, the bloomer or gymnasium skirt is strongly recommended, but not insisted upon. This, which it was difficult to get them to start, has now so become the thing that girls will appear in them of their own accord after three or four visits.

When the number coming for treatment became too large to be properly handled in one class—I do not like to have more than twenty-five together, and prefer fifteen—division was first made on the basis of variety of curvature, irrespective of age or intelligence. But this was found to be unsatisfactory, because the method of instruction and degree of efficiency possible in a child of eleven would distinctly hinder the progress of a girl of fifteen, and it was soon recognized that much of the kind of work which was beneficial for purely postural deformities was equally valuable for partially fixed cases. So division has been made into three classes about as follows:

Class I, children and those just past puberty, who are beginning treatment; Class II., children who still require more treatment after they have obtained sufficient ability and understanding of their exercise to advance them to work with the older girls, and all older girls or boys who are beginning treatment; and Class III , made up of all, but especially the cases of greater deformity, who, having acquired a proper degree of general muscular development, are given harder work. This class, which, in its present personnel, I have the pleasure of demonstrating at this convention,[1] have had a general development which has changed several of them from sickly, anemic, and deformed patients into healthy and more or less robust boys and girls who, if they have not eliminated all trace of their curvatures, are at least better able to bear the burdens of life free from the reasonable fear that their deformity will increase. I do not know of any treatment other than systematic exercise which will accomplish this. This class I consider fit subjects for heavy apparatus work.

An adaptation of Swedish Educational Gymnastics is the form used. In the system of Ling, as many of you know, the "day's order" is divided into eleven forms of exercise, to include all portions of the body, and so arranged as to vary with consecutive lessons, according to a logical progression of difficulty of performance and requirements of previous training of heart and lungs, as well as of the general motor apparatus. This system was chosen because: (1) it was believed to be conducive to the greatest accuracy of position, (2) by the use of command more than demonstration of exercise, the conscious assumption of correct positions, trains the nervous system clear back to the highest intellectual centers, and (3) in its method of neuromuscular training by means of forced position holding, rather than by continuous rhythmic motion, the surgeon is enabled to correct any faulty position at once. Soon after the work was begun an additional practical reason for its use was found in the adoption in the New York Public Schools of Swedish educational gymnastics, so that those patients who were fortunate enough to be in a school where a little exercise had been crowded into the course,

[1] A class of twenty-five was presented at the Hospital for Ruptured and Crippled.

were already acquainted with something of the commands used.

The class work is entirely without apparatus. The bare-floor space and the employment of pure body mechanism, bone and joint leverage is all that is depended upon for resistance to muscular action. It must be remembered that much of the light dumbbell and Indian-club drill now in vogue tends to develop the arms and forearms out of proportion to the trunk; but trunk development is what we seek, and the weight of the head and of the extremities forms all of the *weight-arm* resistance required, when the body is placed in appropriate positions. It should not be inferred, however, that the use of horizontal bars, rings, and of the heavy lifting weights that Teschner advocates are not conducive to good, and even more rapid, results, after fundamental posture-concepts have been acquired by the patients. In private practice we can oversee each motion made. But the individual supervision required of the surgeon makes it inapplicable to group work.

The actual make-up of the drill will vary day by day according to the principles of progression above alluded to, but follow strictly the same sequence as to kind of exercises. Thus, after a few quick arm and leg movements to stimulate attention, a formal exercise to increase all diameters of the thorax by overextension of the upper spine is given in various ways. After this come forcible arm thrustings to act upon the muscles with vertebro-scapular attachments. Then come balancing exercises to train the coordination of the muscles about the hip, knee, and ankle, and incidentally of the lower back. After this, the muscles of the lower dorsal and the lumbar regions receive particular attention. Stress is laid upon this variety of exercise, and progression is made as rapidly and accurately as possible. Exercises for the abdominal muscles follow. These are found to constitute a valuable therapeutic agent in overcoming the slouching postural lordoses so commonly associated with round shoulders and even with kypho-scoliosis. In lateral trunk flexions, the danger of increasing the curve mechanically by bending to the wrong side is overcome by noting for each patient, at the time of examination, which side-bending tended to improve the curve, and by placing her accordingly in one or the other line in the class, where she soons learns to bend to her own side only. A little brisk marching, or a run and a deep respiratory movement, last of all, leaves the patient with a general sense of well being, and the treatment is over for the day. One class averages from thirty to forty minutes. Allowing five or ten minutes between classes for the change of clothes, three classes and the individual work are completed in two and one half hours, and all the patients are treated at each time.

Every exercise and every position thus assured, attains as nearly as possible a typical perfection, but particular stress is laid upon the pose of the back and chest. To maintain a given posture absolutely, the entire attention must be concentrated upon the parts so held, especially when this posture is unusual, and anything which diverts the attention weakens the control. One authority has said that the movement of an eyelid affected the posture of the body. These positions oft assumed become habitual because the entire mechanism controling them has been changed. Possibly the physiologists may one day prove to us that these underlying nerve changes, as well as the muscle changes, are entirely organic, and have an anatomic basis.

Of the 199 patients examined during the time mentioned, 44 have found it impracticable to take the gymnastic treatment, leaving 155 who have had this treatment. Of these the greater number, 115, have had class work only, while 40 have had both class and individual work.

The length of time given to treatment varies, but it is found that the simpler postural cases have required from two to five months, and the severe ones six months to a year, before it is possible to say that they have passed the place where it is reasonable to expect that the deformity will not become worse. It is not thought desirable to keep them longer than a year.

It is difficult to state results accurately because the patients often simply stop coming without giving the surgeon an opportunity to finally examine them.

But the following may be stated of the 155 reated: Thirty have been definitely discharged—15 as cured, 14 as much improved, and one unimproved, because insubordinate. Fifty-two have discontinued coming to the clinic, and later enteries show in their histories, 44 cases improving, 4 not yet improved, and of the remaining 4, no entries. Seventy three of the 155 might still be considered as under treatment, though but little more than half that number are regular. Thus, out of 82 patients who are no longer under treatment, 73 are known to have been cured or improved

Summary.—1. Varying conditions among curvature cases do not prevent efficient work in groups of fifteen to twenty five, but a gradation according to age and ability to work is necessary when many patients are treated.

2. The class method ensures the treatment of many more patients than would be possible by individual supervision of exercise.

3. The Swedish educational gymnastics is used because well adapted for these three objects: (*a*) To isolate activity in groups of muscles; (*b*) the immediate and effective correction of faulty positions; and (*c*) the development of intelligent and purposeful cooperation of the patient.

4. Nearly all of those who faithfully pursue the treatment show marked improvement.

THE ETIOLOGY OF YELLOW FEVER.[1]

ABSTRACT OF THE REPORT OF THE COMMISSION OF MEDICAL OFFICERS, MARINE HOSPITAL SERVICE, DETAILED BY AUTHORITY OF THE PRESIDENT TO INVESTIGATE THE CAUSE OF YELLOW FEVER.

THIS report embodies the work of the Commission in fairly testing the claim of Professor Sanarelli of Bologna, Italy, that the bacillus icteroides is the cause of yellow fever, and the conclusion is drawn that this famous scientist has isolated the true cause of the terrible scourge.

This conclusion is based upon a careful bacteriologic study, in the well-equipped laboratory of the Marine Hospital Service in Havana, Cuba, of twenty-two cases of disease thought to be yellow fever by the native physicians in attendance. Of these patients all were seen during the progress of the disease, and in fourteen of them the Commission concurred in the diagnosis. Each case was the subject of careful bacteriologic study before, and, if practicable, after death. This consisted in the abstraction of blood in sterile bulb-tubes from the ear tip under careful asepsis. This blood was then diluted in the bulbs with meat-peptone bouillon, and after an incubation of twenty-four hours the growth was transplanted to fresh tubes of bouillon, from which, after twenty-four hours, Petri plates were made in series. From these the organisms present in the blood were isolated in pure cultures, and studied. After isolation each organism was subjected to cultural examination on all media, by means of which those meeting the demands of Sanarelli for the organism he discovered were readily selected and their pathogenicity for animals established.

Of the fourteen cases diagnosed as yellow fever, the Commission isolated the organism of Sanarelli, the bacillus icteroides, from thirteen, and in the patient in whom this organism escaped the observation of the Commission it was isolated by an independent observer for whom tube cultures had been taken at an autopsy conducted by the Commission. Thus the even percentage of isolation has been obtained in these fourteen cases, all of which presented prominent symptoms of the disease. In the cases not thus diagnosed the organism of Sanarelli was not obtained. From the living blood of twelve of the fourteen patients, abstracted not earlier than the third day of the disease, the organism was isolated, and in the two others it was obtained post-mortem.

The Commission, having preserved a number of cultures made at the Isolation Hospital in the City of New Orleans from patients seen during the epidemic of 1897, also isolated therefrom the bacillus icteroides in the proportion of 83.33 per cent. of the cases examined, the cultures having been made at autopsy. Thus the identity of the bacillus icteroides of our Southern States, with that found in Cuba, and that sent the Commission by Professor Sanarelli, which was obtained in South America, was established.

As a control to these examinations the Commission made use of a number of patients suffering from diseases other than yellow fever, from whom the blood, extracted in the same manner and treated in the same way, failed to yield any organism at all comparable to Sanarelli's. These diseases were representive of those usual to the City of Havana, and were seen during the same period of time in which the cases of yellow fever were under observation.

Also there were thirty-one dead bodies examined, bodies dead from known and unknown diseases, many of them in the city morgue, the most of them in the Spanish military hospitals. In each instance careful section was made and the blood from the heart, from the liver, the spleen, and the kidneys, urine, and feces, planted directly in bouillon or upon agar agar slant tubes, from which cultures series of plates were made. All bodies thus examined, at times many hours after death, yielded colonies of various organisms, save one, and this at the time of autopsy was diagnosed pathologically as yellow fever, and was sterile.

In none of these cases of comparative autopsic examination was the bacillus icteroides found; neither in their blood, nor urine, nor feces. Therefore, the Commission assumes that the organism of Sanarelli is found only in bodies sick with or dead from the disease—yellow fever, at the same time conceding that in many of the sick the blood does not yield the germ, and that in the dead it may prove absent only under certain conditions.

Coincident with the above observations the Commission carried on the study of the natural history of the organism as to its mode of entering the body, its colonization therein, its toxic possibilities, and its distribution in the organs post-mortem.

[1] Under date of November 8, 1897, Passed-Assistant Surgeon (now Surgeon) Eugene Wasdin and Passed-Assistant Surgeon H. D. Geddings were detailed by authority of the Secretary of the Treasury and the President as a Commission to investigate in Havana the nature of yellow fever. Their full report, dated July 10, 1899, has been received and is printed as a separate publication.

Numerous and interesting experiments were made with animals, the Commission finding all the animals at its command, such as mice, rats, dogs, cats, guinea-pigs, rabbits, and monkeys, quite susceptible to the artificial infections produced by inoculating them under the skin, intraperitoneally and endovenously. At the same time it became convinced that the same, or very similar results were obtainable by the use of other organisms of different kinds. It found, as had been claimed by Sternberg, that similar clinical and anatomical results could be found after the artificial administration of the bacillus *x*, as well as that of Havelburg, and of the bacillus coli communis, all of which proved, when artificially exhibited, very pathogenic to all animals; and autopsies upon these revealed similar conditions in the organs. Moreover the toxins elaborated *in vitro* by the above-named organisms, *x*, Havelburg, and coli communis, and icteroides, were precipitated, purified, and tested comparatively upon animals, with the result that the Commission decided that the *mode of death* from these toxins, when injected into animals, *was the same in kind*, and that the toxins differed only in intensity, and that of them the bacillus icteroides was the most potent.

From these facts the Commission, early in their work, became convinced that the claim of Professor Sanarelli, of having discovered the germ of yellow fever, was not established by any evidence presented in his published works, and that it was not tenable so long as it could be claimed that the bacillus of Havelburg and the bacillus *x* of Sternberg produced the same pathological conditions when artificially inoculated, and the Commission recognized the validity of this claim, in view of the facts given above, although it had for a long time recognized both of these organisms as belonging to the colon group.

At this stage of its work the solution of the problem seemed very remote, but before turning to some other and unknown cause of this disease it was determined to place experimental animals under *natural conditions of infection*, since it was recognized that all preceding experimental work was so artificial that it was impossible for the Commission to judge of the pathogenic, or rather *specific* merits of the three prominent organisms. From this animal experimentation the Commission proves the *natural specificity* of the organism of Sanarelli, the absolute *innocuousness* of the bacillus coli communis, of the bacillus *x*, and of the bacillus Havelburg, to even the most susceptible of animals; and a marked degree of similarity in the reaction of these animals (mice) to the *acute infectious organisms*, such as bacillus typhosus and bacillus cholera suis, when exhibited to them naturally. The Sanarelli organism is thus eliminated from the colon group and associated with the acute infectious organisms.

The Commission recognized that Sanarelli's claim was *only* one of *pathogenicity* and not of *specificity*; that until such demonstration of specificity there could be no *valid* claim for his organism. This validity the Commission believes to be established by the conclusion that the bacillus icteroides is "naturally infectious to animals, the degree varying with the species. In some rodents local infection is most quickly followed by blood infection, while in rabbits and dogs there is no evidence of this subsequent invasion of the blood, monkeys react to the infection the same as man does."

The Commission has determined "that the infection takes place by way of the *respiratory tract*," and that the primary colonization in the lungs is responsible for the first evidences of absorptive intoxication such as fever, pains, etc., characteristic of the disease. Also that this primary colonization in the lungs and its toxic symptoms may constitute the *entire attack* of the disease in many instances, an attack so light, so ephemeral, that even the most expert diagnosticians may not differentiate them from other ephemera, or poorly marked attacks of allied diseases, as for instance, *dengue*. Moreover, the conclusion has been reached that what is known in the literature of yellow fever as the "reactionary fever," the "secondary infection" (from micro-organisms normal to the body), and the "secondary paroxysm," is due to the passage of the infecting germ, the bacillus icteroides, from its primary colony in the lungs into the general circulation, thus producing the "secondary paroxysm" so familiar clinically in all marked cases, unless they are of the *siderant* type. This "secondary paroxysm" is then a septicemic one, and it depends not upon the bacillus communis, or bacillus proteus, or upon the micro-cocci, but upon the further colonization of the specific organism in the blood, thus bearing out Paget's observation that the "*decline*" *of the fever* the true "secondary paroxysm," is as *specific* as the "rise" or the primary attack. The Commission recognizes the coincident invasion of the blood by the organisms of the respiratory tract, as of possible, it may be frequent, occurrence, among which are found colon and proteus; or these may invade from the alimentary canal "during the last hours of life," when the mucosa becomes impaired from stasis, such mixed septicemia being of the most severe type and frequently fatal.

The Commission, therefore, differs entirely from Professor Sanarelli in his theory that yellow fever is primarily a septicemia. Indeed, it can scarcely be a matter of surprise that Sanarelli formulated this

opinion seeing that he always produced, with (as he thought) unimportant exceptions, *artificial infections* by internal inoculations, which perforce must have produced septicemia. Those cases not open to such explanation, which he observed in man, he explained in a still more unsatisfactory way; in fact by the assumption that the germ elected to hide away in the spleen in small numbers during the *whole course* of the disease, only to come suddenly forth and produce a septicemia at its termination. The Commission, therefore, concludes that the theory of Sanarelli in this regard is not sustained by the facts of these cases, and offers the above probable solution of the most widely and generally observed characteristic of yellow fever, the "secondary paroxysm" characterized by a septicemia.

The theory formulated and expressed by Dr. Sternberg, U. S A., that the "germinal principle" in yellow fever is to be looked for in the alimentary tract, an opinion evidently dependent upon the well-known influence of the disease upon the organs adjacent and contributive to this tract and portions of the tract itself, as the duodenum, has been found untenable by the Commission, since there is no record of any one ever having isolated the specific germ from this canal save in the case of its presence there through some capillary hemorrhage into its lumen.

The influence of the various disinfecting agents upon the bacillus icteroides has been studied by the Commission with an eye to the practical advantages to be derived from a better acquaintance with the organism, and it is found that the organism is readily influenced by the mechanical and chemical agents in ordinary use. Cold, however, is not a factor in this process, for the organism resists the most extensive refrigeration, and no reliance can be placed on this mode of disinfection. On the other hand, the organism is very susceptible to dehydration and cannot withstand artificial drying for more than ten or twelve days, and it is very probable that its susceptibility to *frost* is due to the lessened humidity of the atmosphere at such seasons rather than to the degree of cold experienced. Sunlight is very fatal to this organism and, no doubt, is more so if the organism has lost its vitality through evaporation of its fluids as in a frosty atmosphere.

The resemblance between the bacillus icteroides in its behavior on certain media and the bacillus of hog cholera has been brought to the attention of the Commission, and it has deemed the observation that there is a possible similarity in the pathogenicity of the two organisms in the domestic hog of great importance, although its experience in the observation of the cultural similarities leads to the conclusion that they are culturally distinct; while the infection of the domestic hog, in its experience, is impossible by the method pursued of feeding the bacillus icteroides to them. However, the question being of too much importance to be determined without full data, the Commission placed under treatment a number of domestic hogs, in an environment free from suspicion of the possibility of any contamination with the bacillus cholerae suis, with a view to deciding the question of the reaction of these animals to the bacillus icteroides, administered to them in pure cultures in their food. These experiments were conducted at the United States Quarantine Station at Delaware Breakwater and therefrom it is deduced: first, that the domestic pig is incapable of infection from the bacillus icteroides when introduced through the intestinal or digestive tract; and second, that the bacillus icteroides when fed to pigs will not produce any of the lesions or intestinal symptoms of hog cholera.

CONCLUSIONS OF THE COMMISSION.

1. That the micro-organism discovered by Professor Giuseppe Sanarelli, of the University of Bologna, Italy, and by him named "bacillus icteroides," is the cause of yellow fever.

2. That yellow fever is naturally infectious to certain animals, the degree varying with the species; that in some rodents local infection is very quickly followed by blood infection; and that while in dogs and rabbits there is no evidence of this subsequent invasion of the blood monkeys react to the infection the same as man.

3. That infection takes place by way of the respiratory tract, the primary colonization in this tract giving rise to the earlier manifestations of the disease.

4. That in many cases of the disease, probably a majority, the primary infection, or colonization in the lungs, is followed by a "secondary infection" or a secondary colonization of this organism in the blood of the patient. This secondary infection may be complicated by the coinstantaneous passage of other organisms into the blood, or this complication may arise during the last hours of life.

5. That there is no evidence to support the theory advanced by Professor Sanarelli that this disease is primarily a septicemia, inasmuch as cases do occur in which the bacillus icteroides cannot be found in the blood, or organs in which it might be deposited therefrom.

6. That there exists no causal relationship between the bacillus "*x*" of Sternberg and this highly infectious disease; and that the bacillus "*x*" is frequently found in the intestinal contents of normal animals

and of man, as well as in the urine and the bronchial secretion.

7. That, so far as the Commission is aware, the bacillus icteroides has never been found in anybody other than one infected with yellow fever; and that whatever may be the cultural similarities between this and other micro organisms it is characterized by a specificity which is distinctive.

8. That the bacillus icteroides is very susceptible to the influence injurious to bacterial life; and that its ready control by the processes of disinfection, chemical and mechanical, is assured.

9. That the bacillus icteroides produces *in vitro*, as well as *in vita*, a toxin of the most marked potency; and that, from our present knowledge, there exists a reasonable possibility of the ultimate production of an anti-serum more potent than that of Professor Sanarelli.

CLINICAL MEMORANDUM.

SUBCUTANEOUS EMPHYSEMA OCCURRING DURING THE ACT OF VOMITING.

By A. W. DUNNING, M.D.,
of St. Paul, Minn.

Mrs. C., a married woman, aged twenty-eight years, has always been in good health, has had no severe illness, and so far as is now discovered is free from tuberculosis or other pulmonary or bronchial affection. Has one child two years old, and is now four and a half months pregnant. During the early part of the present pregnancy she was troubled very much with nausea and frequent attacks of very severe retching. On May 2d, when three-months' advanced, she experienced one of these attacks, felt a sharp pain in the left side of the neck just external to the lower portion of the sterno-cleidomastoid muscle, and immediately following it there appeared an enormous swelling covering the entire side of the neck. When I was called to attend her a few hours later the neck had the appearance of a very much exaggerated case of adenitis, but on palpation it was discovered that the swelling was entirely emphysematous. By the following day it had become diffused so that crepitation could be distinctly felt over the entire left side of the face to the lower border of the orbit, and down over the clavicle to the anterior angle of the axilla. It also extended around the neck to the right side of the face (but in a less marked degree), and down the neck nearly to the points of the scapulæ. By the third day the swelling had subsided considerably, but during another attack of severe vomiting it again returned, and was even greater than before. From this time on, however, it gradually subsided, until at the end of ten days it had entirely disappeared. The only inconvenience which she suffered was a burning and uncomfortable sensation over the emphysematous area, and a feeling as though there was a large collection of gas in the stomach. She would ask her friends to strike her a smart blow between the shoulders, when she would immediately "belch wind" and be relieved for a time, when the occurrence would be repeated. For several days a distinct soreness was felt at each act of deglutition at the point where pain was felt at the outset.

I report this case simply because of the unusual occurrence of the phenomenon, never having myself seen or heard of a parallel case. I will not, attempt, however, to offer any explanation of the manner in which this phenomenon was brought about, but will leave that part of it for your consideration.

MEDICAL PROGRESS.

Inspection of the Stools.—Schutz (*Berl. Klin. Woch.*, June 26 and July 10, 1899) thinks that a more careful inspection of the stools passed in intestinal diseases would in many cases give information as to the exact seat of the lesions. The most important consideration is whether or not mucus is present. A small amount may be physiological, as that which coats hard fecal lumps. Mucus with constipated stools indicates catarrh of the large intestine. To determine from the mucus in diarrheal stools whether enteritis exists, or there is simply a dyspeptic diarrhea, is a more difficult matter. Evacuation of pure mucus without feces, and consolidation of mucus about small fecal masses, means catarrh of the lowest portion of the intestine. An intimate mixing of mucus and feces indicates an involvement of the upper part of the large intestine or of the small intestine. The presence of undigested muscle fibers, or starch granules, associated with mucus without fever, indicates disease of the small intestine. Besides these general laws, one may draw valuable conclusions from the consistence, amount, color, and smell of the mucus. In certain cases simple microscopical or chemical examinations will be necessary to determine the presence of blood, pus, bile, etc.

Why Does the Surgeon Fail to Find the Appendix?—Scott (*Bull. Cleveland Gen. Hosp.*, April, 1899) asks this question, and in order to answer it he wrote to most of the surgeons and anatomists of the United States. From the replies received as well as from a study of the literature he states that he has collected data representing 10,000 operative cases and an equal number of examinations of cadavers. In no less than twenty-nine (29) instances did the surgeon, recognized as a capable one, fail to find the appendix, although the operation was performed in the interval, whereas only five (5) times among the 10,000 observations upon the cadaver was the appendix wanting. In no one of the latter cases, however, was the examination so thorough as to absolutely prove the congenital absence of the appendix. How, then, explain the great discrepancy between the records of the surgeon and those of the anatomist? He had a case of appendicitis obliterans totalis occurring in his own practice, in which the appendix was so small and so closely bound down to the posterior abdominal wall that he would not have discovered it had it not been for an enlarged lymphatic gland which lay close beside it. Ap-

pendicitis obliterans totalis seems to him to offer a scientific explanation of the discrepancy between the observations of the surgeon and the anatomist. Obviously the former is lacking in his opportunities for making a thorough search in his care for the life of the patient. The literature records no case which is not more practically explained on this hypothesis than on the supposition of the congenital absence of the appendix.

The Origin of Pain in Gall-Stone Colic.—BERTELSMANN (*Mün. Med. Woch.*, June 20 and 27, 1899), after careful investigation of the above subject, comes to the conclusion that true colic of the gall-bladder may occur without inflammation and without obstruction. Inflammation may be the first cause of colic by stimulating the bladder to contractions. It may, however, merely accompany the same. Inflammation increases tremendously the pain caused by contraction, but contraction alone may also give colic. While admitting that colic in most cases is accompanied by inflammation the author repeats his firm belief that it may occur in a severe form without it.

Four Cases of Infantile Monstrosity in the Same Family.—HESTLE (*Va. Med. Semi-Monthly*, June 23, 1899) relates the following interesting and peculiar history: A mulatto girl, healthy and well-formed, was married to a strong, healthy negro, aged twenty-five. Her first child was stillborn at about the seventh month. It was a male and had neither arms nor legs nor auricular appendages. The hands and feet were well developed and attached immediately to the well-developed body. The following year she was delivered of a normal, healthy, female child. The third birth was of the same character. At the fourth, fifth, and sixth labors she gave birth to monsters exactly like the one at the first labor. They were all males, and the arms, legs, and auricular appendages were in each instance absent, the hands and feet being attached to the body. About the third month of the first pregnancy her brother entered her room at midnight with a living opossum, which he threw on her bed, frightening her very badly. From that time on she suffered much uneasiness lest her child should be deformed. Nothing unusual occurred during the remainder of her term. While pregnant with the second and third children she was not frightened at all. During each of the last three pregnancies she was frightened about the third month of gestation by seeing an opossum and she suffered from an almost constant fear that the child would be deformed. This fear was naturally much stronger after she gave birth to the second monster. It is well known that the legs of the opossum are very short and his feet, therefore, close to the trunk, while its auricle is rudimentary and almost invisible on casual inspection. Hestle does not attempt to explain the connection between the fright and the birth of the monsters, but considered the remarkable coincidence as worthy of note.

The Pathology of Gas-poisoning.—SMITH (*Brit. Med. Journ.*, April 1, 1899) had opportunity to make exact examination of the blood of five persons who died from gas inhalations. The inspired gas contained about sixteen per cent. of carbonic oxid. The results of examination show, without doubt, that the injurious effects of gas are directly attributable to the action of the carbonic oxid and not to the accompanying poisoning. The carbonic oxid is poisonous on account of it affinity for hemoglobin, this being almost 300 times as great as the affinity of oxygen for hemoglobin. In one case the carbonic-oxid saturation of hemoglobin was found as high as eighty-three per cent. The temperature of the body is an important factor in poisoning by carbonic oxid, and the poisoned person should be warmed as quickly as possible by internal and external means. Sometimes the temperature rises very much just before death and this is an indication that the heat-centers have been injured by the lack of oxygen. If the blood absorbs over thirty per cent. of carbonic oxid, slight muscular efforts, such as walking, produce severe headache, so that the patient reels like a drunken man. The patient should be kept absolutely quiet in order to avoid loss of oxygen. Sometimes the carbonic-oxid intoxication produces convulsions and tetanic spasms sufficient to cause the death of the patient several days after he has been removed from the effects of the gas. Pneumonia may also follow, and cardiac affections may arise to interfere with recovery.

THERAPEUTIC NOTES.

Cerebrospinal Meningitis Treated by Lumbar Puncture.—CUTHBERTSON (*Chicago Medical Recorder*, June, 1899) reports three cases of cerebrospinal meningitis occurring in the First Illinois Cavalry, one of which was treated without lumbar puncture and the patient died, while the other two patients were treated with ice to the head and spine, fly blisters on the neck, $\frac{1}{40}$-grain doses of mercuric bichlorid hypodermically, and lumbar puncture. Consciousness returned some hours after the withdrawal of a dram of cerebrospinal fluid, and though recovery was slow in each case it was complete. One patient's progress was retarded by numerous abscesses which formed at the sites of the hypodermic injections.

A Chinese Remedy for Amenorrhea.—HIRTH (*Munch. Med. Woch.*, June 6, 1899) introduced into Germany a remedy for amenorrhea which for more than fifteen centuries has found favor in China in the treatment of female disorders, but especially for amenorrhea and dysmenorrhea. The extract is made from the root of a plant called tang-kui, and as it contains nothing which is poisonous or capable of producing abortion, tests were made of its virtues by MUELLER (*Munch. Med. Woch.*, June 13, 1899) in fourteen cases. In two of these there was no appreciable result. In all of the others, although the medication was combined with hydrotherapy, massage, and the administration of iron, Mueller thought that he could observe the good effect of the drug; that acting as a general tonic, it also brought on the flow at the correct period, besides increasing it and making less severe the premenstrual pain. The refined extract as prepared by Merck is called eumenol.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the Medical News will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, AUGUST 26, 1899.

THE PLAGUE IN EUROPE.

Contrary to the many apparently trustworthy assurances, of experienced sanitarians and well-known bacteriologists, that the civilized world was safe from all danger of the plague in modern times, and in spite of all the precautions taken against it, the plague has succeeded in finding its way into Europe. The occurrence of bubonic plague at Alexandria under circumstances that made its further spread extremely probable was the first serious shock to these complacent prognostics. Nearly one hundred cases have occurred in that great commercial mart so intimately connected with the civilized world, and the end is not yet. The plague at Oporto proves in a similar way not to be merely the occurrence of a few cases among seafaring people. On the contrary, the disease has obtained a foothold in the town itself. Some cases are reported from Lisbon, and the town of Figueira has developed an outbreak of the disease. Various cities in Spain are said to harbor cases, some of which have proved fatal.

It is to be hoped that these rumors are, to say the least, exaggerations, figments of reportorial imagination during the "dry" season, but the conviction is borne in upon us that the quarantine precautions thus far taken are entirely inadequate. It is interesting to note that the *British Medical Journal* prophesied some time ago that the plague would almost surely reach Europe. The course of the disease in the Far East is not unlike that of epidemics that finally became almost universal. Certain it is that the present spread of the disease is sufficient to arouse the medical world, at least, from its fancied sense of security.

In India where, despite all the sanitary, hygienic, and prophylactic measures that have been taken, it has continued to rage for nearly five years, the plague is now actively spreading at the following places: At Hong Kong, where from thirty to forty deaths and as many new cases are being reported each week. Complaints are heard from Canton of the spread of the disease from the island to the mainland, and the threatened invasion of the city of Canton itself. Plague has existed for some time on the island of Madagascar, and has lately, according to a French official announcement, spread to the neighboring island of Reunion, where over thirty new cases, and nearly as many deaths per week, were reported as occurring at the end of July and the beginning of August. In German East Africa, where Koch reported that he found an endemic focus of the disease two years ago, the disease is raging with great virulence. At Bukota, East Africa, out of a native population of 715, there have been during the past year 467 deaths from plague.

Here in America, notwithstanding the existence of plague at Alexandria and at Oporto, our danger, as we have pointed out before, seems to be rather on our Western coast. The increased commerce of our Western seaports with the East and the existence of plague at so many points make imperative the most thorough and efficient quarantine throughout our Western coast. Europe stands between us and danger from the East; self-preservation must arouse her soon to efficient work.

THE LOCAL ERADICATION OF MALARIA.

We noted in a recent issue the fact that a party from the Liverpool School of Tropical Medicine, headed by Surgeon-Major Donald Ross, was about

to start for South Africa. The object of the expedition is to demonstrate the feasibility of the local eradication of malaria in some of the South-African villages. Dr. Ross in his inaugural address at the Liverpool School (*British Medical Journal*, July 1, 1899) avers that they have good hope of accomplishing this purpose which if successful will revolutionize the conditions of living in tropical countries.

Dr. Ross has shown that the intermediate host of the malarial hematozoon is the mosquito; not any or all mosquitoes, but a particular genus. The ordinary domestic mosquito, for instance, *culex pipiens*. does not carry malaria. In Dr. Ross' experience it has always been the rarer genus *anopheles* in whose tissues he has been able to demonstrate the malarial parasite. In the mosquitoes of the genus *culex*, though placed under the most favorable conditions for carrying malaria, he has never been able to find traces of the parasite. These observations are confirmed by the results of investigation in Italy, where Grassi, Bignami, and Bastianelli have succeeded in cultivating the germs of human malaria in mosquitoes but always in individuals of the genus *anopheles*.

Now it happens that the breeding-places of *anophelidæ* are stagnant pools usually limited in extent. They never breed successfully where there are minnows since minnows devour the larvæ with avidity. They breed especially in water-tanks, small reservoirs, in puddles, in small undrained swamps where fish never penetrate. Their larvæ were found by Ross in India in tubs and barrels and even in an old abandoned boat. The eradication of their breeding places ought not to prove a difficult task if seriously and intelligently attempted. Ross admits that to get rid of the ordinary mosquito would be a hopeless undertaking but he considers that the elimination of the malarial bearers from a neighborhood may prove comparatively easy.

The prospect opened up by his observations is certainly encouraging. The means he proposes for the eradication of malaria are comparatively so simple that one is tempted to think that in certain localities of our own country, or in some of the villages of Cuba and Puerto Rico, the plan of draining the small bodies of stagnant water might help in the demonstration of the truth or falsity of his views. Ross himself calls attention to a fact that has often been noted before with regard to the distribution of malaria, namely, that certain, sometimes very limited, parts of a malarial district are much more affected than others. It is evident that narrow local conditions are the cause of this, and Ross' hope as to local eradication of the disease by simple drainage would seem not to be unfounded.

MORE LIGHT ON THE PATHOGENY OF YELLOW FEVER.

WE published two weeks ago in our editorial on "Sanarelli and the Pathogenic Rôle of the Bacillus Icteroides" the announcement that the Commission of Medical Officers of the Marine Hospital Service, detailed by authority of the President of the United States to investigate in Havana the nature of yellow fever, had declared that Sanarelli's bacillus icteroides was undoubtedly the cause of the disease. The information came to us through Sanarelli himself, with whom the officials of the Marine Hospital Service had been in communication, and anticipated all publication of the Commission's results in this country. We are glad, however, to be able to present our readers this week with the details of the Commission's report as it contains statements of great interest.

There seems to be little room for doubt as to the pathogeneity of the bacillus icteroides in yellow fever after reading the account of the observations made by the Commission. In every one of fourteen cases diagnosed clinically as yellow fever the microorganism described by Sanarelli was isolated. It was not found in a single case of illness that had not the clinical symptoms of yellow fever, though it was looked for in a number of cases. Culture observations and experiments show that the bacillus isolated from yellow-fever cases in Cuba is the same as that found in yellow fever in New Orleans and in Brazil. The identity of the disease in all these places is absolutely determined.

The Commission announces definitely its opinion that the infection of yellow fever takes place through the lungs. This conclusion will come, we think, as a matter for distinct surprise even to those most familiar with the disease. Gastro-intestinal and hepatic symptoms so crowd the field of vision in severe cases of the disease that the prevailing impression that yellow-fever organisms began and ran

their course in the digestive tract was most natural, and has been the accepted theory.

In following the literature of yellow fever in South-American countries we have pointed out the fact, noted first in Brazil, that it was especially among molds that the bacillus icteroides grew most luxuriently. Last week we quoted some further work of Dr. de Lacerda on this subject with Sanarelli's Comments, that this symbiosis with molds would serve readily to explain the fact, now pretty effectually established and generally admitted, that yellow fever can be an air-borne disease. Primary infection through the respiratory tract becomes still easier to understand under these conditions.

The work of the Commission is especially interesting in its relation to the claims made by Dr. Caldas, a correspondent in Brazil from whom we print, in this issue, a letter with an abstract of a report made by him to the Academy of Medicine in Rio Janeiro. The United States Commission found that as regards most features of their pathogeneity for animals it was impossible to distinguish from one another, Sternberg's bacillus *x*, Havelburg's bacillus, the ordinary bacillus coli communis, and Sanarelli's bacillus icteroides. The "*mode of death*" from the toxins of these various bacilli when injected into animals "*was the same in kind*," the toxins differed only in intensity, and the toxin of the bacillus icteroides was the most potent. The Commission, it is true, found reasons later that justified it in separating Sanarelli's bacillus from the other micro organisms which are all evidently of the colon group, but their original observations remain of interest.

Now Dr. Caldas, our Brazilian correspondent, claims that the bacillus icteroides is a modification of the colon bacillus, which develops when that micro-organism is grown in the presence of certain molds, especially penicillium and aspergillus. We are, of course, here in the presence of that *crux* of present-day bacteriology, the question of the possibility of the transformation of a non-pathogenic into a pathogenic bacillus, or of one form of pathogenie into another. It is to be hoped that the present communications and the workers they stimulate may serve to throw some light on it, for it is one of the most important questions that bacteriology has to face at the present time.

THE "INDEX MEDICUS" AND THE TWO ENGLISH-SPEAKING MEDICAL ASSOCIATIONS.

It has been definitely announced that unless some sure means of providing for its financial support could be secured the *Index Medicus* must cease publication. This declaration has been greeted with sincere expressions of regret from every quarter of the medical world.

Various methods have been discussed in Germany by which a periodical to replace it might be established, to be published, of course, in the German language. The editor of the well-known *Gazette Medicale de Paris* thinks that the periodical to replace the *Index Medicus* should be published in French, and he has recently made an eloquent appeal to French medical men for funds for that purpose.

It would be unfortunate, indeed, if this great help to the medical profession everywhere, as well as in England and America, should cease to be published in English. An appeal has already been made to the American Medical Association (at the recent Columbus meeting) to take upon itself the expenses necessary for the publication of the *Index*. *The Medical and Surgical Review* of London suggested recently in an editorial that the *Index* was a matter of interest to all English-speaking medical men, and that the British Medical Association should unite with the American Association for the worthy object of guaranteeing it financial support. The suggestion is an eminently fitting one, and seems most opportune. While the American Medical Association is well able to take upon itself the pecuniary burden of the *Index* should it see fit, still it would be a most graceful act for the British Medical Association to offer to share that burden.

We were of the impression that this matter of the *Index* was to be formally presented to the British Association for action at the recent meeting. Published accounts so far give us no inkling on the subject.

We hope that the opportunity was not neglected, and shall confidently look for the heartiest cooperation in this matter from the two Associations—a cooperation that will do much to draw English-speaking medical men closer together, while serving to perpetuate a most useful and labor-saving work for the medical profession of the world.

ECHOES AND NEWS

Beri-Beri in Mississippi.—Two cases of beri-beri have been reported at Biloxi, Miss. The disease has heretofore been practically unknown in that region.

Post-Mortem Honors.—Some time after his death the Liverpool Samaritan Hospital for Women elected the late lamented Lawson Tait consulting surgeon to the hospital.

A Tablet in Memory of Dr. Love.—The Board of Governers and the medical and surgical staff of the Mountainside Hospital in Montclair have had placed on the walls of the hospital, in the main corridor, a tablet in memory of the late Dr. Love, first president of its medical and surgical staff.

Dr. Frank Donaldson Appointed Assistant-Surgeon of Volunteers.—Dr. Frank Donaldson of New York, Assistant-surgeon to the "Rough Riders," who did such excellent work in caring for the men at Montauk Point, has been appointed Assistant-Surgeon of Volunteers, and expects soon to go out to the Philippines.

A Hospital at Des Moines.—A hospital will be built this fall under the auspices of the Methodist Church, at Des Moines, Iowa. It will be conducted on non-sectarian lines. The buildings will cost $100,000 and an endowment fund of $100,000 will be provided. The Methodist Conference of Iowa now pays more than $10,000 annually to hospitals outside the State.

Another Stomach Removed.—On June 9th last Kocher removed the entire stomach of a woman, aged forty, who had cancer of the pylorus, uniting the duodenum and esophagus and suturing the abdominal wound over a small glass drainage-tube. The patient lived three and a half days after the operation. Autopsy showed some peritonitis as a result of necrosis of a small portion of the wall of the transverse colon.

Obituary.—Dr. William D. Hartman, who had been in active practice for some sixty years, died at Westchester, Penn., last week at the age of eighty-four. He was well known for work in conchology and entomology. His writings, especially on mollusks, are well-known in Europe as well as this country. He was a member of the Pennsylvania State Medical Society and ol the Chester County (Pa.) Medical Society.

The Plague in Italy.—As we go to press there are persistent rumors though they are being denied, that the bubonic plague has found a foothoid in the south of Italy and in Sicily. A number of cases, some of them fatal, are said to have occurred in Naples and Palermo. At Oporto in Portugal the situation is not so threatening as it seemed last week, but few new cases are developing and most of them are of mild type.

Tuberculosis in Italy.—Senator De Renzi, in a recent speech at Naples, declared that tuberculosis has cost Italy two million lives during the past thirty years, and last year alone (1898) killed fifty thousand persons. The Duchess Ravaschieri has presented to the Neapolitan Home for Incurables her fine villa at Pozzuoli as a sanatorium for tuberculosis patients. It is said that the villa is most favorably located, and could not have been better fitted internally for a sanatorium had it been specially built for that purpose.

The Twentieth Century No-Horse Chaise.—A writer in the *Echo medicale du Nord* compares the expense to a country doctor of a team and that of a motor tricycle. The figures are real, being taken from the actual experience of a physician of Buis. Putting the initial expense of two horses with necessary harness and carriages at $660, he estimates the running expenses at $480 a year. The tricycle cost him $500, and its keep cost $150 annually. To this sum must be added $30 more which the physician spent for carriages in very bad weather. With the motor tricycle he traveled 20,000 kilometers (12,427 miles) over roads decribed as "terrible," without a single serious accident.

A Congress for Dispersing Hailstones by Artillery.—An assemblage under this title is shortly to meet at Casale Monferrato, Italy, and a large number of medical men, engineers, agriculturists and meteorologists have announced their intention to read papers and to participate in the discussions, among which the question above indicated is down for consideration. It seems that there have been an unusual number of fatalities in Italy during the present summer from lightning. The storm cloud from which the lightning comes is almost invariably charged with hailstones, and it is now suggested that the bombardment of such clouds hitherto successful in protecting vineyards and olive plantations, might also lessen the danger from lightning.

Inseparable Twins.—Toward the end of July a pair of joined twins somewhat resembling the Siamese twins were presented before the Academy of Medicine of Rio Janeiro, Brazil. They were united by a band of soft tissue at the upper part of the abdomen, posteriorly and laterally. The members of the Academy agreed that an operation for the division of the band seemed feasible. All the important organs of the two girls were fully developed and seemed independent. The operation was attemped July 29th in the presence of many of the most distinguished surgeons of Rio Janeiro. Incision into the band revealed the fact that the kidneys of the twins extended through it and that its division might prove fatal. The operation was abandoned after the exploratory incisions and no evil effects have followed from it.

Typhoid Fever in Paris.—As Paris is to be crowded next year with visitors from all over the world her sanitary condition is a matter of universal interest. The present state of the city with regard to typhoid is not encouraging. It was thought that the supplying of all quarters of the city with water from municipal sources would lead to the gradual diminution and practical disappear-

ance of the disease. The water-supply is now in working order in practically all parts of the city, but the expectations as to typhoid have been disappointed. Professor Thoinot at a recent meeting of the Société des Hôpitaux reported that there had been in 5⅓ months from January 1st to June 10th, 248 deaths from typhoid. This is 9.8 per 100,000 and this is as many as occurred during any twelve months between 1894 and 1898. Thoinot claims that the increase of typhoid is due to neglect of the water-supply and the use in certain quarters of the city of other than the regular city water.

A New Law for Canadian Barbers.—In the Province of Quebec, Canada, a law goes into effect on September 1st, according to the provisions of which no barber is allowed to take up the practice of his profession—or begin business—until he has passed an examination before the Graduate Barbers' Union and received a certificate from the Barber's Association of the Province. Every candidate must satisfy the Association that he has served for three years as an apprentice at the trade. He must also bring a certificate from a physician in good standing, that he is suffering from no contagious disease. Besides a rigid examination as to his ability to fulfil the manifold duties of the *tonsorial artist*, the candidate is obliged to answer a series of questions with reference to the hygienic precautions necessary to prevent the spread of any contagious disease from one customer to others. This quizzing includes especially the sterilization of instruments and towels and the proper use of toilet preparations and instruments, so that by no possibility can they become conveyors of infection.

Major Russell Harrison's Illness.—Major Russell B. Harrison, the son of ex-President Harrison, who is Inspector-General of the United States troops at Santiago, Cuba, is reported suffering from yellow fever at Cristo, the point to which headquarters were removed from Santiago when yellow fever became epidemic among the troops quartered in that city. Recent reports seem to indicate that Major Harrison is on the road to recovery though at first it was reported that he was critically ill. His was one of President McKinley's appointments from civil life during the war that caused great dissatisfaction. Major Harrison had had nearly ten-years' military experience in all ranks of the National Guard of Indiana up to lieutenant-colonel and he did much at once to disarm public comment by his success in maintaining discipline when he was appointed provost-marshal of the Seventh Army Corps at Jacksonville, Florida. His work in the same capacity in Havana gave great satisfaction and at Santiago he was looked upon as a most capable and efficient officer. The favorable reports of his condition are especially welcome.

A Sanatorium for Consumptives versus a Man of-War.—Some time ago the Portuguese Minister to Brazil suggested a contribution from the Portuguese residents of that country in order to make a present of a warship to the mother country. Some 500,000 milreis (about $275,000) were subscribed. The sum was, of course, totally inadequate for the construction or purchase of a modern warship of any importance. Queen Amelia of Portugal who is greatly interested in the health of her people, so much so that on more than one occasion it has gone the rounds of the medical journals (as our readers may remember) that she had a diploma in medicine, now proposes that the money shall be used for the building and furnishing of a sanatorium for consumptives. It is said, however, that there is some objection to this on the part of the subscribers. We can only commend Queen Amelias' humane thoughtfulness. It is in line with the efforts that are being made by all the European governments and it is a significant index of the temper of the modern rulers and their feelings toward their people. We sincerely hope that the charitable purpose of the Queen will not be thwarted.

The Plague at Various Points.—The bacteriological examinations by the Pasteur Institute of material sent from Spain leaves no doubt that the disease spreading in Portugal is the true Eastern bubonic plague. In India, according to the *British Medical Journal*, the plague continues to spread at Poona to an alarming extent. During July 29th and 30th, 360 cases occurred, and 317 deaths. Five Europeans are numbered among the victims: Lieutenant MacLeod, Miss O'Gorman. Mr. and Mrs. Stephens, and Miss Bartley. Of these, the last named is reported to have died. The largest number of cases have occurred in the city, but the cantonment is also seriously stricken. The dryness of the season is causing great distress, and, as the meteorological conditions indicate the close of the monsoon, the prospects are considered ominous. Plague has reappeared in epidemic form in Bangalore, and a great exodus of the inhabitants is reported. In Persia plague exists and is spreading, while the fanaticism of the inhabitants prevent the enforcement of sanitary precautions that would limit the spread of the disease. The mullahs and the people of Bushire telegraphed to the Shah on July 25th, demanding the abolition of the plague measures. The populace have wrecked the telegraph wires, and so threatening is their attitude that the British Consul has advised his countrymen to avoid the native town. In Egypt the outlook as to the eventual suppression is more hopeful than it was. During the week ending August 2d, 6 cases of plague occurred in Alexandria. Since the beginning of the outbreak 37 cases have proved fatal, 39 have recovered, and 4 cases remain under treatment. The sanitary authorities have the work well in hand, and no effort is being spared to eradicate the disease. From Hong Kong the latest news is much more encouraging than recent reports have been. The *British Medical Journal* says "a marked decrease of plague in Hong Kong is reported, during the past week only 30 cases and 30 deaths being officially reported. It is only two weeks ago since we had to report over 100 deaths a week. The officials hope that the outbreak will soon entirely disappear." At Mauritius the state of affairs has grown worse and the type of disease there is very virulent. A recent telegram has been received by the British Colonial office from the governor of the island, reporting the

occurrence of 52 cases of the disease during the first week in August, of which 37 have proved fatal.

OBITUARY.

PROFESSOR BUNSEN, the distinguished chemist and, at least, honorary member of the medical profession, died at Heidelberg, August 16th, in the eighty-ninth year of his age. His father was the distinguished Professor of Occidental Literature at the University of Göttingen at the beginning of the century, and a great antiquarian who had many friends in England. Professor Bunsen is most popularly known as the inventor of the Bunsen burner and the Bunsen electric battery. He has been Professor of Chemistry at the University of Heidelberg since 1852. He organized the magnificent chemical laboratory of the University and made its courses in chemistry the best known in Europe. It was here in conjunction with Kirchhoff, the Professor of the Physical Sciences at the same University, that he made the great scientific discoveries of the spectroscope and the possibilities of spectrum analysis. Nearly sixty years ago he announced before a meeting of the British Association for the Advancement of Science at Glasgow his discovery of Kakodyl, a compound containing over fifty per cent. of arsenic and yet possessing no poisonous properties. It is only during the last year or two that the possible alterative value of this compound has been developed, especially by French physicians. He was the joint discoverer with Berthold of the hydrated oxid of iron as an antidote for arsenic.

Medicine has lost in Bunsen one who has made very important, practical contributions to the century's advances in medical matters. He received the honorary degree of M.D. in 1875.

MEDICAL MATTERS IN NEW YORK.

A LIQUID-AIR CREMATORY — ARRESTED FOR PRACTISING MEDICINE ILLEGALLY—A NEW HOSPITAL—DR. WOODBURY TO WITNESS GERMAN ARMY MANEUVERS — A TELEPHONE TALK — EXPERTS ON CHARITY—OBITUARY.

A COMPANY has been formed in this city for the purpose of cremating dead bodies through the agency of liquid air. The crematory will be erected near Nyack.

Dr. A. M. Petrella of 178 Sand street, Brooklyn, was arrested on August 19th for practising medicine illegally, in that he had failed to register with the Health Board. This is his second offense. He is said to be a graduate of the University of Naples and to have been at one time Mayor of Padua, in Italy.

The Beth Israel Hospital Association, by its President, Harris Cohen, has filed plans for a six-story and basement brick fire-proof hospital building, 100x78 feet, which will be erected on the northwest corner of Jefferson and Cherry streets, at an estimated cost of $100,000.

The German Emperor has given Dr. John McG. Woodbury of New York, recently appointed by President McKinley United States Commissioner to investigate the medical methods of the German army, permission to witness the maneuvers of the Sixth Army Corps at Silesia in September. The doctor will thus have an opportunity to inspect the practical operation of the medical department of the German army.

Dr. Brown, a colleague practising in this city, met with one of those contingencies which probably very few men have the good fortune never to have experienced. Funds were low, and collections had to be made. So he made a list of those of his patients whose accounts were very long overdue. Among these was one Mr. Jones, who owed $25, and whom Dr. Brown telephoned as follows:

"Br-r-r r-r." "Hello!"

"Is Mr. Jones in?" "Yes."

"Please tell him Dr. Brown is at the 'phone."

Presently came Mr. Jones, who began cheerily: "Hello, old man. What's up?"

"Can you send me $25? I—— "

"Why, certainly, old man ——"

"I thank you kindly."

"Don't mention it, old boy. Say the word, and we'll double it. Where'll I send it?"

"To 411 West 44th street.

"Where?"

"411 West 44th street."

A pause.

"Who is this?"

"Dr. Brown."

"Oh. I thought this was my friend Brownell. Just excuse me a moment, Doctor, until I look at my checkbook."

Another pause.

"I am really very sorry, Doctor, but on examination I find my account at the bank overdrawn. At the very first opportunity, etc., etc."

Comptroller Coler has written to the State Charity Aid Association asking for suggestions in line with a general reform of the present system of appropriating public money for charity. The Association appointed a committee consisting of George F. Canfield, Charles S. Fairchild, Gertrude S. Rice, Alfred T. White, and Homer Folks to investigate the subject and prepare a reply. The committee has prepared a complete plan for dealing with the question which is embodied in a long letter sent by the Association to the Comptroller in answer to his request.

It is recommended that all appropriations of public money to private charities should be made in the general budget, and that the excise and license funds should be paid into the general fund for the reduction of taxation. No appropriation should be made for the support of any person until the city's Department of Public Charities has investigated the case and reported that the person in question is properly a public charge. All payments should be made on a per-capita basis, and public money should not be paid to private institutions in a lump sum. All institutions should receive the same rate of payment for the same class of inmates.

It is recommended that "appropriations to dispensaries might wisely be discontinued, though, in order to prevent

hardship, each institution might receive in 1900 one-half the amount received by it from city funds during 1899." If, however, it should be decided not to discontinue appropriations to dispensaries, the following regulations are suggested:

"That no new dispensaries be added to the list receiving public funds.

"That no dispensary should receive in any year from public sources more than one-half the amount received by it during the preceding year from voluntary contributions, nor, in any event, should it receive more in one year than it received in 1899."

When the city maintains institutions in its own Department of Public Charities for special classes of cases, and these institutions are not filled, the city should not pay for the same class of cases elsewhere.

The private institutions that are now receiving city money are divided into eleven classes and the amounts they will receive this year are as follows:

	Number of Institutions.	Amount.
Children's Institutions	51	$1,665,723.76
Infants' and Foundling Asylums	7	551,050.18
Maternity Hospitals	12	54,822.78
Hospitals	60	271,550.40
Dispensaries	33	37,904.35
Reformatories for Women	6	40,604.08
General Relief Societies	22	19,250.70
Homes for the Aged	15	20,796.32
Corporate Schools, mandatory	28	205,000.00
Institutions for Defective Children	15	206,197.33
Miscellaneous	33	176,723.91
All Institutions	282	$3,249,623.81

It is strongly urged that the city should keep a close watch and check upon all private institutions receiving public money.

Dr. Andrew K. Smith, a retired surgeon of the United States Army, died suddenly on August 15th. The doctor was a native of Connecticut. He was appointed Assistant Surgeon in 1853. He was retired in 1890 after "long and faithful service," with the brevet of Lieutenant-Colonel. Since his retirement he has practised medicine in this city.—Dr. James L. Kortright, formerly a resident of Brooklyn, died on August 15th at Middleton, whither he had gone because of pulmonary disease. Up to a year ago the doctor was one of the visiting staff of St. Catherine's Hospital, Brooklyn. Dr. Nathaniel Wilson Leighton died at his home in Williamsburg on August 15th. He was sixty-six years old. He was physician and surgeon at the Kings County Hospital in 1859 and later at the Eastern District Hospital. During the Civil War he fought for three years and saw service in many engagements. After the war he practised in Brooklyn and was United States pension examining-surgeon from 1866 to 1885. Dr. Leighton was a member of the Kings County Medical Society, the New York Medical Association, and the American Medical Association. He was a delegate to the International Medical Congress of the Pan-American Congress.—Dr. Tunis L. Schenk died on August 16th at his home in Brooklyn. He was graduated in medicine in Syracuse and was for some time Chief Surgeon and Physician at the Kings County Hospital. Dr. Schenk's ancestors had been long established in Kings County.

The Health Department of New York City makes the following report for the week ending August 19, 1899: Measles, 106 cases, with 7 deaths; diphtheria, 136 cases, with 25 deaths; laryngeal diphtheria (croup), 7 cases, with 5 deaths; scarlet fever, 61 cases, with 2 deaths; chicken-pox, 5 cases; tuberculosis, 181 cases, with 138 deaths; typhoid fever, 61 cases, with 17 deaths; cerebrospinal meningitis, 6 deaths.

MEDICAL MATTERS IN CHICAGO.

ANNOUNCEMENT OF CHICAGO COLLEGE OF PHYSICIANS AND SURGEONS—VITAL STATISTICS—INVESTIGATION AND VERDICT IN THE FLANDERS CASE—BLASTOMYCETIC DERMATITIS—STATE SANATORIUM FOR THE TREATMENT OF POOR CONSUMPTIVES.

THE eighteenth annual announcement of the College of Physicians and Surgeons of Chicago, the School of Medicine of the University of Illinois, sessions of 1899-1900, differs slightly from its predecessor. The fall term opens Monday September 18, 1899, with the presentation of diplomas and certificates of scholarship for admission to the college. April 18, 1900, is the day set apart for the commencement exercises. On April 19, 1900, is the opening day of the last spring term that will be given by this college, it having been decided that the best interests of the students will be conserved by conducting a continuous course. Beginning the first Monday in September, 1900, the work of the college will be continuous. The collegiate year will be divided into three terms of four months each, beginning respectively the first Monday in September, the first Monday in January, and the first Monday in May, and called the Fall, Winter, and the Summer terms. Each term will consist, as nearly as possible, of a session of sixteen weeks.

Each student will be required to attend two terms of four months each, in order to receive credit for a year's time. A student may receive credit for no more than two-terms' attendance in any calender year. However, a student may attend a third term in any year, provided he has the permission of the Dean and the written consent of his physician, for which attendance he will receive no credit for the time, but during which he may receive credit for work done. Four-years' time, that is, attendance upon eight full terms, will be required for graduation. The shortest interval between a student's matriculation and his graduation cannot be less than three years and eight months.

In addition to the change to the continuous course, the requirements for admission have been materially increased, necessitating a higher degree of knowledge and ability for one contemplating the entrance to the medical profession

According to the weekly bulletin of the health department, the one satisfactory feature of the public health situation continues to be the low relative rate of infant mortality. At this season of the year deaths under one year of age usually average more than one-third of the

total number of deaths. During the week ended July 15th, the second week of the volunteer medical work among the young of the congested wards, the total deaths were 559, of which number 216, or 38 per cent., were of babies under one year of age. In the succeeding weeks the proportions have been as follows: Week ended July 22d, 36 per cent.; week ended July 29th, 31 per cent.; week ended August 5th, 29 per cent. Last week, August 12th, of 490 deaths there were 134 of children under one year, or 23 per cent of the total.

It is suggested in the bulletin that these figures show the value of the labors of the volunteer physicians and afford a conclusive argument for making these midsummer sanitary and medical inspections a permanent feature of public health work.

In our last letter to the MEDICAL NEWS (August 12th, page 214) we referred to the death of a Mrs. Flanders, the victim of "divine" healing. Since then an investigation has been conducted by Coroner Ebbe. The verdict of the Coroner's jury was to the effect that Mrs. Flanders died "from peritonitis and puerperal septicemia at St. Luke's Hospital, caused by criminal negligence and malpractice on the part of De Witt C. Holmes and Mrs. H. Bratz." A mittimus was immediately issued and Holmes and Bratz were securely placed behind bars. The case of the State Board of Health *versus* Mrs. Bratz was tried before Justice Everett August 16th, and after hearing much evidence and arguments, Mrs. Bratz was fined $100 and costs for practising medicine without a license, finding that the woman had given medical attention to Mrs. Flanders under the guise of faith cure. Notice was given by the defense that an appeal will be taken to the Circuit Court. It is believed that the outcome of this case is but the preliminary skirmish for instituting other law suits having for their object the extirmination of Dowieism. Dowie's followers consist largely of hysterical women and ignorant, feeble-minded men.

At a meeting of the Chicago Medical Society, Drs. James N. Hyde, Ludwig Hektoen, and Arthur D. Bevan contributed a joint paper on blastomycetic dermatitis, in which they reported a very interesting and instructive case. R. B., aged fifty-seven, day laborer, resident of Chicago and married, presented himself September 30, 1898. He was a native of Holland and came to America in 1892. Mother, and one brother at forty-eight, died of consumption; three sisters also died of the disease. Patient had six children of his own, four living and in good health; two dead from causes unknown. He weighed 99 pounds, a decline from his average weight of 146 pounds. He had been a heavy drinker. About five years ago a small reddish spot appeared on the right leg somewhat below the knee. This gradually extended until it covered practically the anterior surface of the limb and developed into a tender, painful, and hemorrhagic sore somewhat resembling an ulcer. Eventually, under treatment, healing occurred over the entire affected area with the exception of a split-pea-sized patch on the inner aspect of the leg between the knee and the ankle. The result was the production over the region named, with the single exception of the unhealed patch, of a thin, broad, cicatriform tissue, quite superficial, insensitive, and in places scaling. Between one and two years ago the left thumb was found to be involved in a morbid process resembling that first seen upon the leg, a process which by gradual extension from the site of original implication produced a reddish patch well defined in outline, with a bluish-red areola and a decidedly verrucous aspect covering the dorsal face of the left thumb quite as far as the nail border, and also the dorsal surface of the left hand to a point somewhat above the line of the wrist. This was dull-reddish in color, sharply defined in outline, having a peculiar bluish-red border extending about four millimeters away from the edge of the affected area. Body of the patch was made up of an elevated mass of infiltration with a verruciform development of fine, pinhead-size papillæ projected externally.

Dr. Bevan placed the patient on iodid of potassium with the result that the sore on the leg healed, and such material diminution in the size of the patch on the hand occurred with such marked amelioration of all the symptoms that the question of operative interference was for the time set aside. Patient has had exacerbations of his trouble during the intervals when the iodid has been discontinued.

The authors say: "We know that the lesions of actinomycosis sometimes are relieved by the administration internally of iodid of potash. In the light of present experience we now know that blastomycetic affections of the skin sometimes are thus benefited. There is suggested here an interesting possibility or probability that many of the cases heretofore grouped under the known and common forms of granulomata, *i.e.*, syphilis and tuberculosis, or cases mistaken for epithelioma and treated as such are, in fact, due to as yet unknown or little known germ-forms, protozoa, yeast-fungi, or bacteria, and further investigation in this line may lead to the solving of the great problem of the etiology of malignant growths.

"The surface of the skin is covered by an imperfect horny layer of varying thickness, and also by polymorphonuclear leucocytes. In places small abscesses have broken through the horny layer. The striking feature is the hyperplasia of the epithelium in the form of variously shaped branching downgrowths from the interpapillary processes. In many places the picture greatly resembles a squamous-celled carcinoma. Numerous focal collections of leucocytes and miliary abscesses are found in all parts of the epithelial proliferations; in these abscesses we find the organism peculiar to the process; some of the abscesses contain multinuclear giant-cells of the tuberculous type. The tissue between the epithelial downgrowths presents acute and subacute inflammatory changes, but only few characteristic miliary abscesses."

The organisms are found only in the miliary abscesses in the epithelium and always outside of the cells; they are best stained by methylene blue and average twelve mikrons in diameter; they are round or oval, surrounded by a distinct capsule from which the finely vacuo'ated or granular protoplasm is separated by a narrow, clear zone.

The Illinois Society for the Prevention of Consumption

is preparing plans for the establishment of a State sanatorium for the treatment of consumptives, which it will ask the next Legislature to build. The plans are based on the announcement of Dr. J. A. Egan, Secretary of the State Board of Health, that the Board, after investigating the advisability of such an institution, reports favorably.

The fundamental purpose of the project is to provide means for the treatment of the poor who are disabled by the disease. The scheme is the idea of Health Commissioner Arthur Reynolds. Governor Tanner has indicated his intention of supporting it and of approving the purpose of the society in asking for an appropriation of $500,000 with which to build the sanatorium.

The report of the State Board of Health, which is in course of preparation, will state that Illinois stands eighth in the list of States in the proportion of consumptive citizens. It will assert also, that most of the consumptives are poor people who live in the country and cannot afford to attend private hospitals. The hospital at Dunning is declared to be inadequate for taking care of the poor consumptives in Cook County. The result of the investigation is summed up as follows: There are thousands of tuberculous persons inhabiting the tenement districts of the larger cities, and also distributed throughout the State, unconsciously disseminating the germs of disease among their own kin, friends and neighbors, and thus jeopardizing the public health. It is believed that many such afflicted persons are curable if properly cared for, and, aside from a humanitarian view, that the restoration to health of disabled breadwinners and protection to communities from infection by tuberculous patients would be of great financial benefit to the State.

CORRESPONDENCE.

YELLOW FEVER, AN INFECTION PRODUCED BY MALIGNANT COLON BACILLI.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—I have the honor to send you with this a monograph of mine on the etiology and serum-therapy of yellow fever. According to the conclusions that I have reached you will see by this publication that I do not recognize the specificity of Sanarelli's bacillus in yellow fever. My researches seem to point rather to conclusions that this disease is a form of infection with colon bacilli, rendered malignant by special circumstances; that it is, in a word, a form of colon bacillemia (French, coli-bacillose).

Seeing the interest the MEDICAL NEWS takes in yellow fever I have thought that you would be desirous of giving your numerous readers the opportunity to know my conclusions. I enclose a communication on this subject presented by me some time ago to the National Academy of Medicine of Rio Janeiro, Brazil, and to the Pasteur Institute of Paris and remain

Yours etc.,

DR. PHILLIPE CALDAS.

RIO GRANDE DO SUL, BRAZIL, July 14, 1899.

[Dr. Caldas' inclosure is interesting because it is a serious and, to the eyes of its author at least, successful attempt to prove practically that interesting theory so often discussed in recent bacteriology, that bacilli may be polymorphic; that is, may exist under different forms, having special virulence in each form. It is an important contribution to the question of the possibility of transformation of a non-pathogenic into a pathogenic bacillus.

Dr. Caldas has found that the bacillus coli communis cultivated in the presence of the micrococcus pyogenes aureus and the streptococcus pyogenes or certain forms of molds, especially penicillium and aspergillus, takes on a very marked change of form. It comes to resemble very much the bacillus icteroides described by Sanarelli. When injected into animals it produces the same lesions as those described after the injection of the bacillus icteroides, especially the fatty degeneration of the internal organs. As it is well known that yellow fever is a mixed infection and that pus cocci are always present in lesions of the disease, and as it is conceded that they are of etiologic importance in the production of certain symptoms at least, the possibility of this change of virulence because of the presence of mixed infection cannot be denied.

Dr. Caldas further quotes the articles by Dr. de Lacerda (which we have abstracted for our readers at various times), who found that the bacillus icteroides grew with special virulence and special luxuriance where molds were present.

Dr. Caldas succeeded, by injections of cultures, of the micro-organism isolated by him, into horses, in producing a serum which was effective for the cure of yellow fever. Of eleven cases of yellow fever treated with this serum eight were in the second stage and were considered very seriously ill. Only two died, a less mortality than attends any other method of treatment. It is true the author adds that two others were actually injected, but as they were moribund at the time they are not allowed to enter into the statistics.

According to Dr. Caldas, then, yellow fever is an infectious disease of gastro-intestinal origin. It is a mixed infection produced by the colon bacillus, a normal saprophyte of the intestinal canal, which, when allowed to grow in the presence of the stapylococcus pyogenes aureus, or of the streptococcus pyogenes, or both these micro-organisms, in a culture-medium containing molds, changes its morphologic properties and becomes a terrible pathogenic agent, the microbic cause of yellow fever.—EDITOR.]

THE YELLOW-FEVER QUARANTINE IN VIRGINIA.

LETTER FROM NEWPORT NEWS.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—A telegram from Surgeon-General Wyman on Monday asking me to take a hand in the yellow-fever crisis here found me shortly afterward making a house-to-house inspection of the towns along the Chesapeake and Ohio Railroad, between Williamsburg and this place. The object of this house-to-house inspection was to locate any suspicious cases of sickness in the little villages and the country adjacent. These towns are so

situated that they offer a natural outlet for refugees from Hampton and Phœbus. Persons desiring to get out of the infected regions, having gotten through the lines, would drive to one of the stations along the line and get their tickets to some place further north, and many hundreds did so in the few hours which intervened before the establishment of a complete condon around Phœbus and the Soldiers' Home.

It is a well-known rule in a district threatened by yellow fever that the limits of clean territory and the district between this and the territory adjudged infected (the so-called Neutral Zone) should be immediately determined. This Neutral Zone (which, in the present instance is that between Newport News and Williamsburg) is to be held as infected, so far as communication with clean places is concerned, and as clean with regard to the infected district.

A thorough inspection of this district in the last few days has failed, I am happy to say, to show a single case of sickness of any kind, and as five days have elapsed since it was possible for anybody to have gotten out of Phœbus and pass through the district, I think we are safe in saying that this Neutral Zone is clean.

There was a good deal of anxiety in Newport News because it was known that people were leaving Hampton in large numbers, and taking the railroad at points along the line; to prevent this, the State Board of Health ordered that no trains be stopped between Newport News and Williamsburg. While this, unquestionably, was necessary during the first three days of the scare, it has not been so since Dr. White declared that this town *was not infected.* The Health Board of Newport News, however, insist upon holding Hampton as infected; and, although the State Health Board sent an inspector who was to require certificates from persons wishing to board the trains, either from the North or South, the Newport News Board of Health has refused under any conditions to allow passengers to be taken on at any point in the Neutral Zone.

Not only passenger, but freight, trains have been forbidden to stop at points in the Neutral Zone, so that provisions have become nearly exhausted in the district, and farmers are complaining bitterly of the loss of their crops, being, of course, unable to ship them north or south.

I think that we have finally convinced the powers that be that there can be no possible danger in putting off freight in the Neutral Zone and taking on the farm products for shipment to Richmond in the one direction or Newport News in the other.

Surgeon Glennan, in his article, entitled "Measures to Be Taken in an Infected and Non-infected Town," in treating of the precautions which should be taken at uninfected places having communication with places which are infected, and with places in the Neutral Zone, says that it is a complex and difficult proposition, and that this is due to the fact that in the several States (Florida excepted), individual counties, villages, and settlements are a law to themselves as regards sanitary matters. Probate judges, mayors, and self-constituted village authorities proclaim a quarantine against the world, and over all this situation State Boards of Health have only advisory powers, and their advice is often received with derision. This is emphasized by the position of the local Board of Health here, with reference to Hampton and the Neutral Zone.

My experience here and last summer at Port Tampa only goes to further convince me that the quarantine organization should be in the hands of the National Marine Hospital Service.

A year ago, for instance, the transport "Santiago," with twenty-odd officers and over a hundred men, all of whom had been desperately ill with either yellow fever, dysentery, calentura, or other of the innumerable diseases which Siboney supplied, was sent from that port to Port Tampa. Although at the time of our arrival at the latter place we had been five days out of the infected district, the State Board refused to allow the officers and men to be taken through the State in a closed train, thereby forcing us to remain ten full days in quarantine at Egmont Key.

Dr. Geddings, who had charge at the Egmont Quarantine Station, speaks in his report of "the pitiable condition" of the officers and men; and I remember only too well the terribly depressing effect which this ten days had upon one and all of us. We should have been sent, without delay, to points in the North. A number of the officers grew steadily worse while we were there, notwithstanding the fact that we had the most devoted attention from Dr. Geddings and every comfort that money could buy, and I know of one brave officer whose death may be directly attributed to the sojourn at Egmont Key, and of a much-delayed recovery in a number of others. It is perfectly evident that the National Government should have had the power to take these men directly North.

The need of a National control again is emphasized by the action of the Norfolk authorities in quarantining against a perfectly clean place like Newport News, against which Newport News naturally retaliated.

Finally, while we are not yet out of the woods, it may safely be stated that the outlook is most favorable.

I would like to say just here that the handling of this whole situation by Surgeon-General Wyman has been absolutely efficient and thorough, and the people owe him a debt of gratitude which I am sure they will only be too glad to acknowledge.

Frank Donaldson, M D.,
Acting Assistant-Surgeon Marine Hospital Service.

Newport News, August 6, 1899.

[This letter was delayed in transmission, but the situation therein described is so typical of what may under existing laws occur at any time in any section of our country that it is interesting and instructive.—Ed.]

OUR LONDON LETTER.

[From Our Special Correspondent.]

THE PORTSMOUTH MEETING OF THE BRITISH MEDICAL ASSOCIATION—SCANTY ATTENDANCE—DISCUSSION OF THE PREVENTION OF TUBERCULOSIS BY CLIFFORD ALLBUTT, SIR WILLIAM BROADBENT, OSLER AND TYSON—REVISION OF PHYSICAL STANDARDS FOR PUBLIC SERVICES—THE DESTRUCTION OF MOSQUITOES—RESULTS OF ANTISTREPTOCOCCIC SERUM—REACTIONARY "ANTI"—ADDRESS OF PRESIDENT OF SECTION ON STATE MEDICINE.

THE attendance at the Portsmouth meeting was pretty much as predicted in our letter written at the close of the first day. Instead of 1800 members, as had been anticipated, the register hardly showed 800 and of these not more than two-thirds were ever present at any one time. The attendance at the general meetings fell rapidly from 250 on Wednesday, to scarcely 100 on Thursday, and a mere corporal's guard on Friday.

And small blame to them; for the weather got hotter and hotter, the rooms were stiflingly close and these sessions have nothing before them except the solemn Addresses in Medicine and Surgery, etc., and such odds and ends of business as the General Medical Council—the Dowager Empress of our medical Flowery Kingdom—allows the Association to have to play with.

Even that redoubtable warrior Mr. Victor Horsley found this year that he could not get any question before the General Session which had not passed safely through the sifting-committee of the Council and been endorsed as proper to be considered by the Session. The attendance at the various Sections, however, though small was of good quality and the papers and discussions interesting and well sustained.

The chief interest of any unusual order seemed to center in two sections, one large and imposing, the Section on Medicine, and the other small and unique, the Section on Tropical Diseases. Two main discussions were taken up in the former, the "Standards of Requirement in Examinations for the Public Services" and "The Preventive and Remedial Treatment of Tuberculosis." The first discussion was opened by the reading of the paper of Sir Dyce Duckworth, followed by Professor Osler and Dr. Wallace. The judgment of all who participated tended strongly toward a rationalization of the present standards, and the relaxation of red-tape and mechanical methods so as to leave more discretion to medical examiners. All agreed that many most valuable candidates and recruits were rejected, merely on account of some slight temporary heart-murmur and albuminuria of adolescence or from failing to reach the milliners measurement of the present standards in some trifling particular.

Dr. Savill in particular criticized the folly of rejecting men on account of the deficiency of a fraction of an inch in height and presented a careful analysis of a number of cases rejected on this ground showing them in chest-measurements and general vigor to be distinctly above the average. The rigid standard of a precise minimum is simply the revival of the ignorant drill-sergeants' preference for "tall fellows" and "even-topped" ranks, for as all anthropologists now know, small men have bigger chests, better muscle and will do more work, on less food in proportion to their size than tall ones. And as mere weight and length of sword-reach have nothing whatever to do now days with winning battles, while toughness, endurance, and resistance to disease and hardship have everything, it is high time this absurd relic of barbarism was modified if not abolished. If a short man has a good chest, legs and *stomach*, and strength enough to march under a rifle, he is just as good a modern soldier as any six-footer can possibly be and will stand thirty per cent. more bucketing about on thirty per cent. less food.

Nearly all the experts who took part, including Surgeon-Generals Moore and Cuffe, insisted strongly upon the folly of sending recruits under twenty-two to twenty-five years to serve in the tropics, and at the close of the discussion a resolution to this effect and in favor of rationalizing the present physical standards was passed, to be forwarded to the War Office.

The discussion upon the "Prevention of Tuberculosis" lasted two days, and was opened by Professor Clifford Allbutt, followed by Sir William Broadbent, Professor Osler, Sir Douglas Powell, Professor James Tyson of Philadelphia, Sir Hugh Beevor, and others. The tone of the discussion was most hopeful, the open-air sanatoria with the encouraging records were well represented and many of the speakers, including Clifford Allbutt himself, ventured to express the hope that even within our own life-times we should see tuberculosis, if not exterminated, at least put in a fair way toward it. Stress was laid upon the increasing cleanliness of modern life as illustrated in the disappearance of domestic parasitic insects, always a dangerous source of infection, and the belief expressed that 'household asepsis" would prove ultimately an even greater benefit than the surgical variety.

Well-deserved importance was attached to the splendid work of Birch-Hirschfeld upon the starting-point of pulmonary tuberculosis, which he found in a large percentage of thirty incipient cases, dead of other causes (out of a series of 4,000 consecutive autopsies at Leipzig), to be one of the bifurcations of a particular bronchus supplying the posterior part of the apical lobe. As the bacilli in these earliest-stage cases are not in the alveoli or the lymph-nodes but just under the bronchial mucous membrane, he believes it to be an aerial stagnation-infection and the apex a point of least resistance in the lung.

Sir Hugh Beevor presented a series of curves and maps showing the death-rate from tubercle under various conditions, all of which clearly pointed to the close connection between tubercle and over-crowding and deficient ventilation. The death-rate rises steadily with the number of inhabitants per room and house. Special stress was also laid by several speakers upon the fact that plenty of fresh air and life in the open was the chief requisite in cure, climate, temperature, moisture, and elevation being minor considerations. As Dr. Hillier expressed it, "climates differ in desirability, simply in so far as they tempt the patient to live in the open air." Provide plenty of home

sanatoria, especially for the poorer classes, and cure patients in the climate in which they have to live and work. Dr. Woods Hutchinson presented tables of measurements of 82 tubercular chests, showing that they have a most uniformly, typical shape, *round*, narrow, and long, instead of *flat*, as usually described. This shape of chest is simply the arrested chest of early adolescence, the thorax failing to complete its development from the almost dog shaped chest of the embryo to the flattened adult human type. Hence any chest failing to develop properly in breadth after fifteen or sixteen years, should be regarded with suspicion and diameter measurements be a valuable guide to the pretubercular state.

As a rule our English brethren seemed to think little of either sputum examinations, which they regard as too uncertain and a great deal of trouble for little benefit, or the diagnostic use of tuberculin. In some of the largest hospitals in London bacteriological examinations of the sputum are made but in a small proportion of cases.

The tone of the discussion upon malaria and its prevention in the Tropical Diseases Section was almost equally hopeful. Specimens of the guilty mosquito (*Anopheles* claviger, and *A. pictus*) and of the various stages of the development of the malarial parasite in their interior were sent over by Bignami and Grassi and made a fascinating display.

High anticipations were expressed of the results of the Liverpool School's expedition to West Africa, headed by Major Donald Ross, which was even then rocking upon the Bay of Biscay en route for Sierra Leone. If as stated by entomologists, the breeding-grounds of *Anopheles* are decidedly limited then some means of eliminating the disease by checking the breeding of its carrier ought certainly to be hit upon by the expedition.

A valuable paper was read by Dr. George H. Nuttall of Cambridge upon the activity of insects as carriers of disease, in which he regards the common fly as one of the greatest offenders in this respect. Experiments by himself upon the transference of various diseases by the bites of pediculi, fleas and bugs had, however, yielded almost entirely negative results in some 250 instances.

Sir Patrick Manson reported an autopsy upon a patient suffering from *filaria nocturna* who had committed suicide during the day-time, and the heart, pulmonary arteries, great vessels and lungs were found simply crowded with embryos while seventeen adult worms were found in a lymph-varix in the pelvis.

In the Section of Obstetrics and Gynecology much interest was elicited by the discussion of Dr. Herbert Spencer's paper on the "Serum Treatment of Puerperal Septicemia." His conclusions were decidedly unfavorable to the treatment which he thought had not lowered the mortality and was sometimes attended with danger. Although he admitted that its use usually lowered the temperature and made the patient feel more comfortable. Drs. Arnold Lea and Whitelocke reported cases in which they had found it of decided benefit, but Professor Murdock Cameron, Dr. More Madden, and Professor Byers tended to agree with the original paper. The latter declared that in spite of asepsis, puerperal fever was in no way diminishing, which if true is a professional scandal and ought to have a Collective Investigation Committee or a Royal Commission turned loose on it at once.

The attitude of the daily press toward the meeting was distinctly different from that of our own in two respects, it was less keen but more respectful. Whether the advantage of the latter balanced the disadvantage of the former is a question. The gist of the General Sessions and the substance of the Address were briefly but well reported, but the work of the sessions was for the most part regarded as "confidential," in other words, too technical.

The only exception was the Section on State Medicine, which was quite fully reported, though this was a pity in one respect, for the President made a most unfortunate and reactionary address, which was thus widely trumpeted abroad. He chose to fall foul of the entire principle of serum-therapy, *because* it was not identical with that of vaccination. Declared its boasted successes were failures, especially in diphtheria, and denounced the reckless slaughter of animals, which so far had "never saved a human life or lightened appreciably the load of human suffering," quite *à la* Lawson Tait, whose spirit must have entered into him. Needless to say it has been welcomed with howls of delight by "antis" of all sorts.

SOCIETY PROCEEDINGS.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-seventh Annual Meeting, Held at Portsmouth, England, August 1, 2, 3, and 4, 1899.

[Continued.]

THIRD DAY—AUGUST 3D.

SECTION ON MEDICINE.

THE second day of the meeting of the Section on Medicine was principally devoted to a discussion of the

PREVENTATIVE AND REMEDIAL TREATMENT OF TUBERCULOSIS.

The large hall in which the meeting was held, was almost inconveniently crowded, and great interest was manifested in the subject.

PROFESSOR CLIFFORD ALLBUTT'S contribution dealt with the modes of infection of the disease, the morbid anatomy of its first stage, diagnosis, prevention, and cure. He made special reference to the treatment of consumptives in sanatoria. SIR R. DOUGLAS POWELL alluded to the advantages of sanatoria in educating the practitioner in the treatment of patients at home, in providing for homeless persons afflicted with the disease, instructing the patient in the discipline of illness. He also referred to some of their drawbacks. PROFESSOR OSLER laid great stress on the repeated examination of the sputum for tubercle bacilli, and said that in his experience—not a small one—the tuberculin test for the diagnosis of early phthisis had been invariably successful. In his opinion the personality of the physician in charge of the sanatorium was the most important factor of the treatment. DR. TYSON referred to the marked decrease in

the mortality from phthisis in Philadelphia during the last twenty years, eight per cent. He thought that the treatment by drugs should not be entirely ignored, and quoted favorable results from the use of creosote. DR. SHINGLETON SMITH rather deprecated the notification of phthisis, hoping that anything of the nature of quarantine of consumptives would be avoided. SIR HUGH BEEVOR concentrated his observations on overcrowding as a cause of tuberculosis, and referred to tables showing the relation of phthisis mortality to density of population. The President, DR. BRUCE, called attention to the prevalence of tuberculosis in the training-ships for boys in the Royal Navy, its probable cause being the retention of the old fashioned insanitary wooden ships, particularly objectionable when used for sleeping quarters. DR. PARSONS considered that in view of the great difficulty in diagnosis of early tuberculosis every apparent cure of a case, prior to the appearance of tubercle bacilli in the sputum, should not be included in statistics. MR. LARDNER GREEN described the use of a spray of dilute formalin as an adjunct to the sanatorial treatment of phthisis patients. DR. DENTON JOHNS distinguished between sanatorial and climatic open air treatment, and discounted the latter in the absence of the former. He showed a patient that had been cured under sanatorial treatment. DR. CALWELL brought forward details of cases that had done well under hygienic treatment independently of sanatoria. DR. BURTON-FANNING stated that the National Association for the Prevention of Consumption and Other Forms of Tuberculosis was just about to begin the building of sanatoria for the London poor.

SECTION ON SURGERY.

The discussion of

THE PREVENTION AND TREATMENT OF SYPHILIS IN THE NAVY AND ARMY

was opened by Deputy Inspector-General E. E. MAHON, R.N., and MAJOR W. DICK, M.B. The former called attention to the following statistics: In 1880, the average strength of officers and men on the home station was 22,370; in 1897 it was 43,900, or nearly double. In 1880 the loss to the service in number of days' sickness from syphilis, primary and secondary, and gonorrhea was as follows:

Syphilis, primary	32,223
" secondary	12,859
Gonorrhea	40,392

In 1897 the loss to the service in number of days' sickness was:

Syphilis, primary	76,335
" secondary	49,764
Gonorrhea	77,034

The figures show what an enormous loss there is to the country through the prevalence of these diseases. He considered that it was impossible to hope that the Contagious Diseases Acts would ever be enforced again. That, however, would be the most effective way of dealing with the question. Failing this the moral elevation of the men themselves must be attempted, and especially the encouragement of sobriety. He emphatically asserted that intemperance was very largely responsible for the number of cases of venereal disease. The following suggestions were made: (1) Good naval barracks to be substituted for depôt ships in all the principal ports. (2) Advice to be given to young soldiers in regard to personal cleanliness. (3) Early marriages to be encouraged, which might be done by offering pensions to the widows of seamen. (4) Pensioners in good health, and not suffering from the sequelæ of venereal disease, to be given preference for civil employment by the Admiralty. Major Dick called attention to statistics, collected at five-years' intervals, showing the increasing number of cases of venereal disease compared with all cases of illness in the army. The percentages for the years 1882, 1887, 1892, and 1897 were respectively 23.66, 26.65, 30.94, and 38 71. It will thus be seen that there was in fifteen years an increase of 15 per cent. of cases of venereal disease. In 1897 the number of cases of venereal disease treated at Netley was nearly one-third of the total number of cases of sickness. The following suggestions were made as to the prevention of syphilis in the army: (1) The inculcation of moral principles in the young soldier. This, though admirable, is theoretical rather than practical. (2) Hygiene of the individual. (3) The rendering of a soldier's life as pleasant as possible in barracks, to prevent his seeking his pleasures abroad in the evenings. Men should be encouraged to come to hospital the moment they themselves detect anything suspicious.

MAJOR LAMBKIN, R.A.M.C., dealt in detail with the intramuscular method of injection. By this method the treatment of syphilis can be continued for as long a period as is thought necessary with little or no trouble to the patient. The following prescription has been employed: Hydrarg., ʒj; lanolin pur., ʒij; ol. carbol. (1 in 20), ʒiv Ten minims are injected in the buttock once a week, and the whole course of treatment lasts about eight to twelve months. In 20,000 injections he had only once seen any bad result—a localized abscess at the point of injection. DR. SHAW MACKENZIE thought that the improvement during the Contagious Diseases Acts was due to the hospital treatment rather than to the machinery of the Acts, and that provision for such hospital treatment of both sexes, voluntary as opposed to compulsory, seems necessary at the present time. COLONEL F. H. WELCH, R.A.M.C., believed that the present state, especially abroad, of the army in its relation to venereal disease, is such as to require measures of prevention. All public measures of prevention must lie in the control of prostitution, and authorities abroad should be allowed a free hand in meeting the local conditions.

MR. A. H. WARD read a paper on

THE RATIONAL TREATMENT OF SYPHILIS.

The following points were considered essential: (1) To push mercury to the toleration point and keep it there; (2) to commence treatment at the earliest possible moment; (3) to continue it throughout the normal period of the evolution of the disease; (4) to make treatment easy and not be irritating; (5) to take special care of the general health; (6) to recognize the value of water as an adjuvant to treatment.

COLONEL FRANCIS H. WELSH read a paper on the

PREVENTION OF SYPHILIS,

which he said can be brought about in two ways—hygienically through curtailing the lineal descent of the virus, sociomorally through curtailing prostitution. The evidence accruing during the last thirty-five years points to the conclusion that through surveillance of prostitution and segregation of the affected it is possible both to reduce the prevalence of the disease and to diminish its virulence. The disease must be attacked from all sides —morally, socially, and hygienically.

PROFESSOR E. LAPLACE of Philadelphia demonstrated a new forceps for intestinal anastomosis. The advantages claimed for this instrument are rapidity of operation, complete and water-tight union of opposed surfaces, and extreme simplicity.

MR. H. RUNDLE read a paper, entitled

NOTES ON 375 CASES OF VARICOCELE TREATED BY OPERATION.

The following inferences were drawn: First, that varicocele exists in a large number of young men, probably 18 to 20 per cent., and does not produce any physical discomfort; that it ought not to be considered a cause for disqualifying them, except in rare and pronounced cases, from entering the service; and, that such ordinary cases do not demand operative interference. Secondly, in cases in which an operation is required, ligature and excision of veins by an open incision is the best. It is a simple undertaking, free from danger and the result is excellent.

MR. JONATHAN HUTCHINSON, JR., whilst fully agreeing that the great majority of subjects operated on for varicocele possess no true pathological defect and suffer no real inconvenience, submitted that in a certain number the persistent aching and the risk of atrophy or softening of the testicle fully justifies the open operation apart from service consideration. He had seen a few cases in which atrophy of the gland followed severe varicocele. He thought some cases, in which the scrotum and cremaster are extremely lax, are only to be dealt with by free excision of the lower part of the scrotum and high ligature of the anterior bundle of veins. MR. J. A. BUCK mentioned a case in which atrophy of the testicle to the point of almost complete disappearance had followed the operation. He advised that only a portion of the veins be excised. COLONEL STEVENSON (Netley) believed that the cases operated on in the services, or the cases of candidates for the services are nearly always less marked than those in civil practice. The testicle is seldom atrophied. It is necessary to operate even on very slight cases in the army because a soldier with any physical disability, even a slight one, is practically useless for duties which he dislikes.

MR. L. A. BIDWELL read a paper on a

METHOD OF ATTACHING THE SKIN TO THE MUCOUS MEMBRANE OF THE RECTUM AFTER PERINEAL EXCISION.

After excising the rectum by the usual perineal racket-shaped incision extending to the tip of the coccyx, two transverse incisions are made on each side of the anus, and the skin flaps are dissected up and attached to the mucous membrane of the rectum. In this way tension is diminished, and it is possible to unite the mucous membrane to the skin even after removal of several inches of the rectum. The duration of convalescence is shortened, the comfort of the patient is greater during dressings, etc., and the chance of cicatrical contraction is lessened.

MR. CARWARDINE (Bristol) described a

METHOD OF EXCISION OF THE RECTUM FOR CANCER,

the aim of which is the safe and complete excision of the rectum, and the contiguous lymphatic area and the functional restoration of the parts. He showed photographs of the various steps of the operation, and a patient upon whom he operated about a year ago. He extirpated the affected gut with the presacral glands and tissue in continuity. A new and bifid coccyx reformed from the periosteum. The operation was carried out as follows: The patient was placed prone, and the coccyx and second and third pieces of the sacrum were excised subperiosteally. Then a long knife was passed through the anus and out in the middle of the periosteum, and all the retrorectal tissues rapidly cut though. The rectum was completely isolated on all sides, avoiding the sphincter. The periosteum was deflected as far as required. Only the mucous membrane was divided above, and the whole presacral tissue and glands drawn down and cut across high up in the hollow of the sacrum. The upper bowel was united to the anus, and with but little drainage the periosteum and soft parts united by first intention. MR. C. RYALL read notes of a case of extensive transacral excision of the rectum, followed by perfect sphincteric control; 12 inches of the upper rectum and lower sigmoid were removed. After two subsequent operations the upper bowel was anastomized to the lower rectum.

MR. JAMES BERRY read a paper on

SEVENTY-TWO CONSECUTIVE CASES OF REMOVAL OF GOITER BY OPERATION (EXTIRPATION OR ENUCLEATION).

In nearly all the cases the operation was performed on account of dyspnea. He drew attention to the serious nature of the goiter in which a prolongation extends down behind the sternum. Many of his cases were of this variety. In ten cases the operation was performed through a transverse skin incision. The results as regards appearance were excellent. Of late he has been in the habit of operating with local anesthesia in all cases in which there is much tracheal obstruction. He reported 3 deaths in 72 cases, one from chloroform, and 2 from severe recurrent hemorrhage. In the remaining 69 cases the immediate and remote results were excellent.

G. E. ARMSTRONG of Montreal, read a communication on the

SURGICAL TREATMENT OF HEMORRHAGE FROM GASTRIC ULCER.

He recorded the results of the post-mortem examinations

at the Montreal General Hospital. In all cases of fatal gastric bleeding the hemorrhage was arterial, and was readily accessible to surgical treatment.

Section on Obstetrics and Gynecology.

In introducing a discussion upon the natural menopause compared with the menopause produced by removal of the uterine appendages, and the menopause produced by removal of the uterus without removal of the appendages, Mr. Bland Sutton remarked that the functions of the ovary are not merely ovigerous; Graaffian follicles are to be regarded as mucous crypts, and the ovary as a ductless gland of the same type as the thyroid. The period of ovarian activity coterminous with that of the menstrual life, and the removal of the ovaries causes not only amenorrhea, but also a series of symptoms characteristic of the menopause. The uterus is structurally a hollow muscle forming an incubation-chamber for the reception and development of oosperms. The endometrium, from fundus to internal os, is the organ of menstruation, and the source of menstrual hemorrhage; but besides hemorrhage there are important vasomotor phenomena in menstruation. The normal menopause is the result of atrophy of the secreting elements of the ovary. In addition to cessation of menstruation, other disturbances are generally met with at this epoch, such as the phenomenon known as "flushing," mental irritability, and sometimes erotomania. The artificial menopause, likewise, is something more than arrest of the usual monthly hemorrhage. Removal of the uterus, although it produces amenorrhea and sterility, does not induce a complete menopause. Removal of the ovaries, on the other hand, is followed in a small proportion of cases by flushings, which he has known to occur as frequently as fifteen times in an hour. These signs do not supervene after removal of the uterus alone. Usually the patient passes through a quiet menopause without disturbances. No information was forthcoming as to the changes which occur in the ovaries left behind after removal of the uterus. Mr. Sutton urged that in peforming hysterectomy one ovary at least should be spared if possible, so as to avoid the production of a complete artificial menopause.

Dr. Reed of Cincinnati said that he agreed with the view that it is an advantage to leave a portion of the ovary if possible, but he sometimes found a second operation necessitated by disease of the retained portion. He drew attention to the importance of further study of the changes in the hematogenic functions at the menopause.

Dr. Stuart Nairne of Glasgow followed with a paper describing a

new and more perfect method of colporrhaphy.

This method consists in uniting the lateral vaginal walls from the cervix to the vulva, so as to divide the vagina into two canals of more or less equal capacity.

Dr. Macpherson Lawrie read a paper on

fifty consecutive cases of celiotomy for diseases of the uterus and appendages, with forty-eight recoveries.

He affirmed that the principal factors on which good results in abdominal surgery depend are: firstly, asepsis, and secondly, careful hemostasis. As secondary points of less importance, he mentioned reasonable speed in operating, avoidance of unnecessary intraperitoneal manifestations, and careful after-treatment.

Dr. Archdall Reid followed with a paper upon the

causes which render difficult the labors of civilized women.

He stated his own view to be that the frequent use of forceps at the present time is rendered necessary by the steadily increasing difficulties attending labor in civilized countries. These increasing difficulties he attributed to the want of correspondence between the size of the pelvis and that of the fetal head, and in minor cases to rigidity of the soft parts. Dr. Shaw-Mackenzie next read a paper, entitled

the syphilitic factor in the diseases of women.

He pointed out the frequency with which pelvic inflammatory disease in parous women is associated with minor syphilitic sequelæ, and for the most part with previous abortion. Syphilis is often modified in women, the primary lesion being of a suppurative character, and the secondary phenomena being limited to erosions of the genital tract with purulent discharge. He advocated the treatment of pelvic inflammation by mercury and iodids. In subinvolution of the uterus that treatment is especially useful as opposed to the curette. In advanced inflammatory or suppurative lesions, however, it is not satisfactory, but in menorrhagia and metrorrhagia it is very useful.

Dr. Warden of Paris followed with a short paper on the

treatment of puerperal infection in the maternity hospitals of paris.

He referred to the importance of the early recognition of the infected state, as indicated by the pulse and temperature, and the importance of immediate local treatment by intra uterine irrigation and careful curetting. The curette should never be used before the third day. Professor Pinard performs the operation without the use of anesthetics. After curettage the uterine cavity is swabbed out with a strong antiseptic, and packed with salol gauze.

Third General Session.

At the General Session on Thursday, August 3d, Dr. Alexander Ogston delivered the Address in Surgery. Departing from the custom of the Association somewhat, instead of reviewing the progress made along surgical lines, he asked whether the advances made since Lister's discoveries have been placed within the reach of the naval and military medical services. There could be only a negative answer to this query, and in the latter portion of his address he outlined some plans to bring about a better state of affairs. He spoke, in part, as follows:

In all the busy centers of the earth is springing up a new race of surgeons, who effect as part of their everyday work marvels of cure that even thirty years ago, had

any one ventured to forecast them, would have been looked upon as the dreams of a visionary. And it is not merely surgery that has undergone a revolution. The discoveries of Lister are changing the aspects of medicine, midwifery, pathology, and many other provinces of medical science. It is, moreover, impossible to avoid the conviction that the open handed beneficence we now witness in the increased interest and support extended to public charities in all their forms has been in no small degree evoked by the great work he has enabled the surgical and nursing profession to carry out.

While, in many respects, we have good reason to praise the age we live in, no one fully acquainted with the state of surgery in our land can fail to be impressed by the fact that some of our medical and surgical brethren are still hampered by systems and restrictions which must be swept away. I venture to believe that in the City of Portsmouth it will not be out of place to advert to the condition of our Army and Navy Medical Services. These, since the surgical world was stirred to its depths thirty years ago by the doctrines of Lister, have been, I fear, gradually falling into a condition that cannot fail to evoke much anxiety regarding their present and future; and it appears to me that the present time is suitable for drawing attention to the reforms that may be necessary to ensure that, when the supreme moment arrives, the medical departments of these services will be found adequately prepared to undertake the duties they will be called upon to discharge. Recent events have demonstrated that we may be unexpectedly called upon to engage with both army and navy in European or even world-wide wars, such as would put their efficiency to the severest possible test.

It is moderate and reasonable to expect that the medical officers of the army and navy shall be able efficiently to perform their functions in time of peace, and fully be prepared for the eventualities of war. Yet no observant member of the profession can have failed to observe that the most talented graduates have ceased to aspire to enter the services; while those medical officers who possess a few-years' experience of the services admit they have made a mistake in entering them, and would gladly, were it possible, sacrifice the years they have spent in them and quit them entirely, even for some comparatively unpromising post in civil life. Consequently, year by year the medical services, especially that of the Queen's Army, have become more attenuated and undermanned. Oft-repeated experience, over the very same ground, has indeed taught us to conduct, in some respects, the medical part of expeditions in the jungles and swamps of West Africa, the deserts of the Nile, or the ravines of the Himalayas in a way that probably no other Power could excel or even equal. Our enemies there are poorly armed and our casualties few. But it dare not be inferred from this that we are in a condition to deal with a war against a Great Power, with arms and organizations at least equal to our own, in which large numbers of wounded—thousands instead of tens—must be treated.

Their duty in time of peace afforded the army and navy surgeon, it is no exaggeration to say, scarcely any chance of acquiring the knowledge and skill that would be demanded of him in war. No surgeon can now, as in former days, rise suddenly out of the ranks of those destitute of special training, however eminent his natural abilities may be. He who is skilled in exercising his profession becomes so by many years of special training. No man who is but theoretically acquainted—be it in ever so perfect a fashion—with the mere doctrines of antiseptic surgery is able to step at once into the arena as a practical surgeon.

A standard of work at least equal in excellence to that of the civil surgeon ought to be expected of army and navy medical officers. Senn of Chicago, Chief Operating Surgeon with the United States Army recently in the field, and one who has done much for surgery, points this out in the following axioms:

1. That in theory and practice military surgery is equivalent in every respect to emergency practice in civil life.

2. That the wounded soldier is entitled to the same degree of immunity against infection as persons in civil life suffering from similar injuries.

3 That all formal operations in war must be performed where the wounded can receive the full benefit of aseptic and antiseptic precautions.

4. That operative interference is indicated in all penetrating wounds of the skull.

5. That gunshot wounds of the chest should be treated under the strictest antiseptic precautions.

6. That laparotomy in penetrating gunshot wounds of the abdomen is indicated in all cases where life is threatened by hemorrhage of visceral wounds, and the general condition of the patient is such as to sustain the expectation that he will survive the immediate effects of the operation.

Statistics show that wounds of the brain, chest, and abdomen form about twenty per cent. of all the wounds received in battle. There must, therefore, in the next great campaign, be an enormous field of usefulness for properly trained antiseptic surgeons, and a fearful waste of life if they be not there to occupy it. Yet who that compares the conditions under which the civil surgeon is formed with those existing in the Royal Army Medical Corps or the Navy will be so bold as to say that the latter furnish any adequate means of familiarizing their surgeons with the highly complicated and difficult procedures which they ought to be able to carry out with dexterity and success? Save a few connected with Netley—and perhaps Haslar—Hospitals, most officers have hardly once in their lives an opportunity of carrying out any important operation on the brain, thorax, or abdomen. How, then, can they undertake, with any prospect of a happy issue, the intricate steps of, say, a laparotomy in a gunshot wound of the abdominal contents, with all its complicated problems and perils? It can hardly be wondered at that a service entailing on those who enter it what is, from a professional point of view, almost an intellectual sterility, should be a mode of life out best graduates recoil from, and which few of them can be persuaded to adopt. Such scientific corps as, for instance,

artillery, engineering, and telegraphy have undergone extensive improvements and reforms in the last few decades. No means of enhancing their efficiency are neglected. For them all the inventions of modern science are studied, adopted, and improved. Tactics are studied, maneuvers held, officers and men practised and drilled, fleets and bodies of men are put in motion, and any unreadiness is observed and remedied. Yet the Royal Army Medical Corps and the Naval Medical Service, which demand a greater degree of practice and experience than either artillery or engineering, ere their delicate machinery can be brought into salutary use, are left in a condition which may have answered well enough fifty years ago, when rough-and-ready surgeons could do the rough-and-ready work then required, but which is out of harmony with the revolutionized conditions of modern surgery and the state of the medical service of the armies and navies of rival military powers. They would seem to be considered as less deserving of development than even such departments as the commissariat and transport —the contemptuous belief being apparently held that trained surgeons to attend the wounded in war can be summoned into the field at a moment's notice by the expenditure of so much money, like the horses, mules, and camels that an army requires.

To manage in this fashion is simply to ensure, when a critical time occurs, a repetition of the scenes of the Crimea, where admirable medical officers were made a sacrifice by the war authorities to appease the public indignation excited.

So complex an organization as the Royal Army Medical Corps ought to be kept in a high state of efficiency, and be vitalized by continual practice. Whether stationed at home or abroad, the officers should be provided with all the proper means of keeping themselves informed regarding the advances that are forever being introduced into their science. Were the reforms that naturally suggest themselves carried out, who can hesitate to believe that the best graduates would once more flock to and remain in them; and the country would not be placed in the dreadful position of having to pay, with the lives of its bravest and best, for the state into which its medical services have been allowed to drift.

More than the army the navy requires the touch of a reformer's hand. In the event of a naval engagement of any magnitude the wounded on board our ships of war would have to be attended to in a small dark room, unprovided with any save the rudest appliances and a few cots, where at most half a dozen men could be handled, and which is, moreover, in many vessels, as much exposed as any other part of the ship to the fire of the enemy. Were such a fighting bay rendered untenable the wounded, however great their need, could be attended to only by being lowered, slung in a vertical posture, down the narrow hatchways, where the shot is brought up from the magazines to the guns, and even these would not be available during the heat of an action. Everything on board ship that can destroy life is in the highest perfection, everything that can save it is of the rudest description and behind the age. We must lead rather than follow in naval matters, as foreign ships of war are constructed according to the example England sets. And our navy, being the most perfect and greatest destroying force of all the war fleets of the world we should be the foremost in introducing into it the best-planned methods of relieving suffering and saving life that can be devised.

Criticisms without suggestions are usually better unmade; and to call attention to defects in the services, without indicating the lines of remedy, would be almost unpatriotic. In countries where universal military service obtains the most eminent civil surgeons are at the disposal of the authorities in time of war, and in peace hold rank in the army, receiving promotion like those actively serving. They are soldiers in reserve and can be made use of wherever their eminence and special qualifications make them most useful in war. The idea of adopting this system among ourselves, but on voluntary lines, is no new one; although it presents obvious difficulties, they do not seem altogether insuperable, and, at any rate, such a plan is worthy of the attention of the War Office.

Much that is instructive may be learned from the medical services of Germany, where, of course, compulsory service exists. Every medical man who has served in the army at all is maintained for nineteen years under military orders—that is, he possesses a fixed rank, and is allotted, even in time of peace, a known military post which he would occupy if war broke out. Thus the university professors hold high military rank, and are required to give annual courses of instruction to the medical officers serving in the army or navy. Such well-known surgeons as Bergmann, Bruns, Trendelenburg, and Mikulicz have to teach these classes during the Easter holidays, so as not to interfere with the winter and summer sessions of the universities. In time of peace German army surgeons have the development of their professional culture ensured by the following measures: The most promising surgeons and assistant surgeons are sent on duty for a year at a time in the medical, surgical, and gynecological departments of the hospitals connected with the universities and in other large public hospitals not connected with them. The junior and assistant surgeons are also annually sent to attend the special courses of instruction in anatomy, surgery, and operative surgery mentioned above. The senior medical officers, nearly corresponding with our surgeon-majors, at least the most competent and promising of them, have to serve in rotation in the large military hospitals, in which are treated, not merely soldiers, but all kinds of ordinary patients; there they have to act as teachers and attend and take a share of the tutorial work among the pupils in the classes of the various professors; or they may be sent on duty for a year in the general hospitals, not only in the surgical, but also in the medical and gynecological wards. They have also to attend, as they may be ordered, annual courses in bacteriology; or they may be furnished with funds for traveling in other countries and studying their medical and sanitation arrangements.

In the Russian army and navy similar care is taken of

the professional culture of the medical officers. Russia possesses 6 large and 300 small hospitals connected with the army, besides smaller lazarettos; and in some of these the equipment is far in advance of anything the services possess in this country. Thus the military hospital of St. Petersburg treats all medical, surgical, gynecological, ophthalmic, and other diseases, consists of five separate clinics or infirmaries, each of which is complete in itself, and has 850 beds, 120 of which are for women, and 20 for children; and about 45,000 patients are treated per annum. In these clinics the students and assistants have to work in the most thorough manner, and study every kind of case. The hospital possesses a staff of 34 professors, 70 *privatim docentes*, and 47 assistants. Each department is furnished with an ample annual allowance for instruments and apparatus, and has liberal provision of everything calculated to assist the most advanced work and investigation; X-ray rooms, photographic rooms, electrical rooms, immersion lenses, centrifuges, etc., to an extent that excites the marvel and envy of British visitors. Russia has 300 surgeons in her army, and any of these may, if he shows ability and powers of work, apply for and be ordered to return to study in the hospitals for a period of two years. There he has to work as a regular assistant, and on proving his capacity may attain a place among the teachers of the institution; or he may be transferred to the hospital of some provincial city, and there continue to perfect himself in his profession, and further qualify himself for his duties in time of war. The Russian naval hospitals are arranged like their army hospitals; they exist in many parts of the empire, there being five large ones at different ports, besides one or two smaller ones; they admit civil cases of all kinds; and in them the medical officers possess opportunities of training themselves in all manner of high-class professional work.

In the French army post graduate courses, expressly for medical officers, are conducted by professors at the different universities throughout the Republic, and the cost is borne by the Army Medical Department; while a certain number of the medical officers of the active and reserve army are every year ordered to attend them, extra pay being drawn by those who do so.

But enough has been said to show that we have much to learn from foreign countries; that, unless we follow their example, our officers, soldiers, and sailors who may be wounded in war will be attended to in a very imperfect fashion compared with those of other European Powers; and that our services stand in need of great reforms, which must be more or less of the following nature:

It would, first, be a great advantage to the services were a Section created for military and naval surgery at the annual meetings of this Association. Such a Section would furnish instruction as to the actual state of matters and what amendments are required. Reforms so initiated and urged on the authorities by this Association could not fail to be quickly introduced. The most clamant of all reforms is provision for the proper instruction of officers in their war duties. I cannot put too strongly the absolute necessity for at least one out of every five years of service being devoted to this. Officers receiving study leave should be sent to act as assistants, residents, and house-surgeons and physicians to our hospitals and schools of medicine, in the same way as our younger graduates who are in training for the highest places in the civil profession.

It is of the most vital importance that the development of military and naval hospitals should at once receive the attention of the authorities. They should, wherever it can by any possibility be done, be thrown open for the reception of ordinary patients from the civil population, and for the admission of diseases of all kinds. The hospitals are the heart of the services, and it is necessary that the authorities should be brought to recognize that this is so, and follow the wise examples set by foreign nations.

Our country ought to provide every fleet with a certain proportion of fast steamers, without armor or armament, flying the Red Cross flag, fitted up with wards, operation-theaters, and dressing-room, anesthetic, sterilizing, and apparatus-rooms, officered by a staff of surgeons and attendants, and in every way imitating the arrangements of the best civil hospitals. These should form as essential a part of every squadron as do the bearer companies and field hospitals of an army. The cost of such vessels would be small compared with ships of war, and the good they would achieve in great naval engagements, and even in ordinary times, would be unspeakable.

The fatal error of imagining that the Army Medical Corps can be supplemented by civil aid is one that has already done infinite harm; it has been made a constant pretext for hindering the due development of the services and producing the defects of which I have spoken, and is a mischievous delusion that cannot be too strongly combated. Were such a proposal made regarding any other scientific department, such as, say, the Royal Engineers, its absurdity would be at once perceived. At its best it is but a poor palliative, but can never be a cure.

I have been moved by the conviction that the present is a suitable time for one who is in the civil part of the profession to speak boldly what is in the minds of many civil surgeons, and is known to still more who are in the services themselves.

But I hope my motives will not be misjudged, and that what has been said may contribute in some degree to stir the profession generally, and this powerful Association in particular, to increased efforts to open the eyes of the British nation to the real state of matters, regarding which it is at present blind; so that when the Temple of Janus once more opens in our midst, the services may be found in such a state of preparation and efficiency as is demanded by the honor and well-being of our country and the interests of humanity.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, SEPTEMBER 2, 1899. NO. 10.

ORIGINAL ARTICLES.

THE RADICAL CURE OF HERNIA.[1]

BY WILLIAM B. COLEY, M.D.,
OF NEW YORK.

IT is impossible to view the present methods and results of the operative treatment of hernia in the true perspective without a brief survey of the past, stopping here and there for a moment to note the more important landmarks. The historical picture presented shows that its evolution has not been a gradual and harmonious development, but rather a series of brilliant conceptions based on more or less sound anatomical principles. At one time these were found commanding the respect and confidence of the leading masters of surgery of the day, and at another relegated to quacks and traveling rupture-curers, who alone kept them from falling into utter oblivion, until, under the new stimulus caused by the great discoveries of anesthesia and antisepsis, they were again revived and elaborated.

While we find occasional references to hernia and its treatment in the writings of the early Greeks, the first recorded description of an attempt to cure the condition by operation was made by Celsus, a Roman, who lived during the first half of the First Century, A.D., and to him must be given the honor of being the founder of the radical cure of non-strangulated hernia. His operation consisted in a free open incision over the hernial tumor, exposure of the sac, and probably the removal of the whole or a part of the sac. If the omentum was present it was pushed back but if irreducible, a needle was passed through the middle and it was then tied off in two portions. The wound was then closed by sutures. The testis was not removed and care was taken not to injure the cord in the dissection of the sac. The operation was confined to children under six years of age.

Heliodorus, who flourished under Trajan at the beginning of the Second Century, has given us a description of a method of operation for hernia which actually surpasses many that are now offered to the profession as new and ideal. He says,[2] "We must cut out the hernial sac with great care for, if you take away less than is protruded, the result will be the production of a new hernia. In order, therefore, that we may not miss excising an amount that is precisely correct it is necessary to draw the sac outward by catching the tip. So soon as the edges of the abdominal wound begin to be everted, enough of the peritoneum has been drawn out and so much is to be excised. When just enough peritoneum has been drawn out the sac is to be twisted. Having been cut off along a straight line the peritoneum becomes folded upon itself, and screwed up and closed so tight that not even the point of a probe can be introduced."

A few centuries later this operation had been abandoned and forgotten.

Paul of Ægina in the Seventh Century, following in many points the method of Celsus, introduced a new and radical step, *viz.*, castration. Without attempting to separate the cord from the sac he transfixed the sac with a "large-sized needle containing a double thread." This thread was then cut and the ends crossed like the great letter X and tied. The portion below the ligature, with the testis and cord, was then cut away. It seems difficult to understand how this method so inferior to the methods of Celsus and Heliodorus should have survived almost to modern times, while the former were so soon forgotten.

During the Middle Ages many new methods were introduced. Castration was still performed though, according to William of Salicetus, only by traveling rupture-curers and foolish physicians. Of the other methods the principal ones were: (1) Exposure of the sac and closure by various forms of ligature. (2) Inclusion of the sac and scrotum either by needles or by sutures. (3) Cauterization applied in various ways. The cure by cautery was known by Paulus and was much employed by the Arabians. It continued in vogue almost to modern times. Full details of the method are found in the writings of Pott.[1] Different writers differed widely as to the extent and depth of the cauterization, but Pott says: "In all of those the exfoliation of the bone is made a necessary part of the process. Eschars and sloughs being separated and the exfoliation cast off the patient is ordered to observe an extremely careful regimen, to lie on his back during the cure and to wear a bandage for some time afterward in order to prevent a new descent of the parts," which notwithstanding all

[1] Address in Surgery delivered before the annual meeting of the Canadian Medical Association, held August 30, 31, and September 1, 1899.

[1] Vol. ii, p. 177.

the pains and all the hazard the patient had undergone he was still liable to.

Cauterization by means of strong acids was also employed. During the Eighteenth Century castration became so common, especially in France, that finally stringent laws were passed condemning it. It is not difficult to understand the dire results that not infrequently followed these methods and which finally led to their abandonment.

Such then was the state of the radical cure of hernia at the beginning of the Nineteenth Century. We find an occasional return to ancient methods in the early part of the present century, notably by the Prussian surgeon, Schumaker, and the elder Langenbeck. They made an open incision and dissected the sac from the cord then ligated it as high up as possible. Langenbeck stated that he had performed the operation twelve times with the most successful results. The method, however, did not meet with general approval and does not seem to have been much employed. With the introduction of subcutaneous surgery by Stromeyer in 1835 there followed attempts to apply its principles to the cure of hernia. The most notable examples were the methods of Gerdy and Wützer, and a little later that of John Wood of London, which was a combination of the open and subcutaneous methods. Wood's operation was introduced in England in 1857, and even to recent times was more generally employed than any other, both in Europe and in America. The best results were obtained by Wood himself who claimed a large percentage of cures. The mortality after this method was about seven per cent., though in his later series of cases it was reduced very considerably.

By modern methods we mean those that have been introduced, or rather reintroduced, since the great discoveries of Lister and Pasteur.

In the first place a distinction should be made between operations for strangulated hernia and those deliberately undertaken for the purpose of effecting a radical cure. Strange as it may seem the operation for strangulated hernia is of much more recent origin than that for non-strangulated hernia. Up to the Seventeenth Century taxis alone had been used for strangulation, and to Pierre Franco, a stone-cutter, must be given the honor of introducing herniotomy in 1652. His minute description of the operation forms one of the bright spots in the surgery of that period. Franco's method was taken up and most strongly endorsed by Ambroise Paré, who first advocated operation for all cases of strangulated hernia. His teaching, however, fell on barren ground, and it was not until two centuries later that herniotomy became generally adopted.

Up to the beginning of the Nineteenth Century it was practically unknown in America. In the life of J. C. Warren,[1] we find it stated that when he began to operate in Boston (about 1804) the operation for stranugulated hernia was unknown. He had just returned from England, and attempted to put into practice what he had learned from his illustrious teacher, Sir Astley Cooper, but when he proposed to operate on a patient with strangulated hernia he was met with the greatest opposition, both from the other physicians and from the friends of the patient. He finally gained consent to operate, but the long delay caused the death of the first two or three patients. Convinced that he was right his genius and courage enabled him to go on, and the brilliant results of his later cases did much toward establishing the operation for strangulated hernia in America upon the solid foundation that it has ever since enjoyed. It does not appear, however, that any serious attempts were made to effect a radical cure until after the introduction of Lister's methods of antisepsis.

Henry O. Marcy of Boston, who had enjoyed the privilege of personal instruction under Lister in 1870, appears to have been the first to operate upon strangulated hernia under antiseptic methods, and to close the inguinal canal by means of absorbable buried sutures of catgut. On February 19, 1871, he operated upon a woman aged fifty years for strangulated inguinal hernia, and closed the canal by "two stitches of medium-sized catgut directly through the pillars of the ring." On March 10, 1871, he operated upon a second patient with strangulated hernia, also a woman, and closed the canal "by three large-sized catgut sutures passed deeply through the pillars of the ring, and the wound was carefully dressed antiseptically with Lister's carbolic plaster."[2] The sac was not opened in either of these cases.

Dr. Marcy's first attempt to cure non-strangulated hernia by operation was on February 4, 1878, or several years subsequent to the operations of Steele, Annandale, and Czerny. Richard Steele of London deserves the honor of first attempting to cure non-strangulated inguinal hernia after the introduction of antiseptic methods, though he very modestly states that it seems such a very natural proceeding he does not doubt that others have done it before him. Steele's patient[3] was a boy eight years of age. He cut down upon the canal, exposed the pillars of the ring, pared their edges, and united them with catgut sutures. The hernia recurred in six months, became strangulated, but was reduced by taxis. Steele

[1] Vol. 1, p. 37.
[2] *Boston Med. and Surg. Journal*, November 16, 1871.
[3] *British Medical Journal*, p. 584, November 7, 1874.

then did a second operation, and the patient was well one year later. This case does not seem to have received the attention it deserved, and to Czerny is usually given the credit of being the author of the modern operation. His first published report described five cases.[1] His first patient was operated upon for non-strangulated hernia January 1, 1877, more than three years later than Steele's. Czerny's operation showed a distinct advance over the operations of Marcy and Steele, *viz.*, he dissected out the sac and ligated it before suturing the canal. From the limited experience derived from his early cases Czerny concluded that the thousand-year-old problem of surgery was nearing solution.

Time will permit but the briefest references to the more important of the numerous methods devised since Czerny's first report. As early as 1879 Tilanus of Amsterdam had collected and reported before the International Medical Congress 122 cases in which operation was performed by supposedly antiseptic methods. Seventy-nine of these cases were non-strangulated and forty-three were strangulated. Too few of the patients had been traced sufficiently long to justify conclusions as to the permanence of the cure, and the immediate mortality of six per cent. made many physicians hesitate to advise and surgeons to perform the operation. The subject, however, was so fascinating and the goal of such inestimable importance that the minds of the leading surgeons of the world were engaged in attempting to modify the old methods or to devise new ones with a view of diminishing the dangers and improving the final result. The methods at present in vogue are the result of somewhat rapid evolution in accordance with the law of survival of the fittest. Not one but many workers in the field deserve lasting honor for the part they have played in conferring a priceless boon upon humanity. Among these names should be mentioned Steele, Czerny, Annandale, Marcy, Banks, Championnierre, MacEwen, Barker, Ball, Socin, Bassini, Bull, Weir, Halsted, and Kocher. These surgeons have apparently worked out their ideas independently, and each deserves credit proportionate to the value of the special features in his method which will survive.

While many of the earlier methods have been superseded by the newer and better, we must not forget that the experience derived from the older methods has made it possible to discover their shortcomings and to devise remedies, therefore let us not refuse them a place of honor. There are still a number of methods in vogue, each of which is represented by its advocate as the ideal operation, and it is clearly our duty to study these carefully and attempt to discover, if possible, the best. I wish the time permitted a full description of these methods because their technic is not always understood by surgeons who perform them.

Were I called upon to give what I believe to be the most frequent errors of technic and those most responsible for failure to obtain good results, I would say (1) an incision of insufficient length, both in skin and aponeurosis (it should be at least three inches long), and placed too low down. (2) Failure to dissect back the aponeurosis of the external oblique well over to the edge of the rectus muscle. (3) Careless or unskilful dissection of the sac from the cord and the surrounding tissues, thus prolonging the operation and bruising the tissues, and thereby lessening the chance of primary union. (4) Too great tension upon the buried sutures, or the use of non-absorbable sutures.

The question of sutures I will discuss later.

I do not need to tell you that the essential feature wherein Halsted's method differs from Bassini's lies in the treatment of the cord and the closure of the canal. In Bassini's method the canal is closed by suturing the internal oblique and transversalis to the shelving portion of Poupart's ligament (which must always be very clearly exposed) the aponeurosis being carefully retracted on either side during this suturing. The rent in the aponeurosis is then closed from above downward as before by means of a continuous suture, until at the lower angle just enough space is left to permit the cord to pass without undue compression.

In Halsted's method, on the other hand, the cord is transplanted more externally, so that it lies just beneath the skin and superficial fascia. The aponeurosis with the underlying muscles and transversalis fascia, on the one side, being united to the transversalis fascia, Pourpart's ligament and the aponeurosis on the other by means of a single row of five or six mattress sutures. One sees at once that if the cord were left in its normal position there would be great danger of relapse at the point where it emerges. To lessen this danger it was ingeniously proposed to remove "all but one or two of the veins of the cord." Whether or not such a procedure might not cause atrophy of the testis was a matter that experience alone could determine. The subsequent histories of Halsted's own cases as well as those of other observers have proven that this result not infrequently occurs.

From a recent and as yet unpublished report of the results at the Johns Hopkins Hospital Dr. Bloodgood has kindly given me the following very interesting and valuable statistics: Of 109 patients operated upon by Halsted's typical method with

[1] *Wien. Med. Woch.*, No. 23, 1877, p. 527.

excision of the veins there was no relapse, while in 86 cases operated upon by the same method with the single exception that the veins were not excised there were 8 relapses or 9 per cent., 56 of these patients were observed from one to nine years. Bloodgood concludes that Halsted's operation with excision of the veins will give perfect results if primary union be secured, though he admits that excision of the veins is liable to be followed by atrophy of the testis and is, therefore, not always to be recommended. He would not excise the veins in children or in patients in whom the cord had been subjected to traumatism during the dissection of the sac. The number of cases in which atrophy of the testis followed excision of the veins is not noted, but it is stated that it was only observed in those cases complicated by epididymitis. Bloodgood therefore reasons that as the probabilities of epididymitis would be much less after excision of the veins, if the vas and its immediate vessels are not displaced, it would be as well to leave the remainder of the cord undisturbed and he goes on to say that "the cord reduced to such a diminutive size will be as little likely to be the cause of a recurrence in the lower angle of the wound as in the upper angle when it is transplanted."

This is practically an admission that one of the leading features of the method, *viz.*, the excision of the veins is not always free from risk, and that another and perhaps the most important, the transplanting of the cord, if they are excised, is unnecessary.

There is another point in which Halsted's method differs from Bassini's, which though seldom mentioned is, I believe, one of great importance, and that is the free division of the internal oblique and transversalis muscles and the transversalis fascia, or in other words the entire floor of the canal as well as the roof. The free division of the internal oblique has, I think, nothing to recommend it, and since gentle stretching of the fibers and pushing them upwards will always permit of the sac being excised well beyond the neck, it would seem unnecessary. We are willing to grant that the union of divided muscular tissue should be firmer than the union of fascia, but undivided muscle should be firmer still. In the event of failure to secure primary union the dangers of relapse are greatly increased, if these deep structures have been divided and the relapse, if it does occur, will almost surely be more serious in character and more difficult to treat.

After all that may be said on either side in the way of theoretical considerations the question of preference must be finally settled by practical results. If the results of several different methods are the same, that method which is the simpler in technic should have the preference. While Halsted's method in his own hands and in the hands of his skilful colleagues at the Johns Hopkins Hospital has yielded most brilliant results, they are not equal to Bassini's personal results. In the results of other surgeons we find a much greater difference in favor of Bassini's method. The technic is far simpler, and we believe the rapidly increasing favor with which it is regarded both in Europe and America shows that it is destined in the near future to supplant all other methods.

It is hard for us to realize that the radical cure of hernia has made such tremendous advances in a single decade. In 1890, Bull, who had faithfully tried the best of the methods then in vogue, and on a larger scale than any surgeon in America (in 134 cases) was obliged to confess that his "observations go to strengthen the conviction that all methods of radical cure will be found unsatisfactory." He did not, however, discourage further efforts to improve upon these methods of operation, but merely wished to depict the situation as it actually existed. He was one of the first to subject operations for radical cure to critical tests and to point out that the term "cure" could not rightly be applied to patients who had merely recovered from operations and had not been observed for a considerable period afterward. To show how rapidly advances have come in this field of surgery, the ink was scarcely dry upon the valuable but gloomy paper of Bull when appeared Bassini's brilliant report of 251 patients, operated upon with but a single death, and all but four of them traced from a few months to four and a half years with only seven relapses. Whether or not these same good results were possible in the hands of other surgeons remained for the succeeding years to tell. Nearly a decade has now passed and few surgeons and still fewer physicians realize the tremendous revolution that has occurred in the operative treatment of hernia. Instead of an operation with a mortality of 6 per cent., alone sufficient to make the conservative surgeon hesitate to recommend it, except in cases of urgent need, and with nearly a half of the cases relapsing within a comparatively short time, what is the situation to-day? We find the mortality of leading operations reduced to less than 1 per cent., and that the final results in large series of cases carefully traced show almost entire freedom from relapse. Instead of 30 to 50 per cent. followed by suppuration we find 5 to 10 per cent. If you will pardon a reference to personal work which is given merely to show what any one may accomplish provided he

gives the proper attention to the technic of the operation I will give a brief abstract of my most recent statistics. Since August, 1891, I have operated upon 639 hernias with one death. These are divided as follows: 585 inguinal, 40 femoral, 14 umbilical and ventral. Of this number all except 60 have been traced. 549 patients with inguinal hernia were operated upon by Bassini's method (with 5 relapses) kangaroo tendon being employed for the buried sutures. Of this number, 493 patients have been traced as follows: 4 were sound after 7 years; 4 after 6 to 7 years; 9 after 5 to 6 years; 19 after 4 to 5 years; 69 after 3 to 4 years; 91 after 2 to 3 years; 132 after 1 to 2 years; 101 after 6 months to 1 year, and the remainder after less than 6 months. In regard to wound healing 96 per cent. of the patients operated upon by Bassini's method healed by primary union. The single death was due to double pneumonia without wound complications.

The only points in which I have departed from the original technic laid down by Bassini have been in the substitution of chromicized kangaroo tendon for silk in the buried sutures. I have recently been told by a former assistant of Bassini that Bassini himself has used chromicized catgut instead of silk since 1892. Second, I have introduced a suture just above the cord, passing it through the same structures as those below the cord, with a desire to prevent any further separation of the tissues above the new internal ring and keeping the cord restricted to narrower limits. That these slight changes, too trivial to be called modifications, have been of advantage the results in my series of operations would seem to prove.

Among the many questions of importance in connection with the subject of radical cure of hernia that are still unsettled is that of the best suture material. Silk, silver wire, catgut, kangaroo tendon, silkworn gut, each one has its ardent supporters. Were the question of less importance I should not attempt to discuss it at this time. Like the choice of operative methods, this question also must finally be settled by careful observations based upon large experience and theoretical considerations must again be placed in the background. Silk was probably used by the ancients. Catgut, introduced by Lister, was probably also first used by Lister to close a hernia wound. Czerny used catgut in his earlier cases, but later owing to the difficulty in rendering it completely sterile, substituted silk. Banks whose name must always be mentioned foremost among the pioneers in operations for the cure of hernia, states[1] that the only point of novelty he could claim in the operation which he successfully performed was in the substitution of silver wire for catgut. He closed the external ring with two or three buried sutures of stout silver wire. Macewen modified the simple catgut suture by chromicizing the gut sufficiently to maintain it in the tissue three or four weeks before absorption took place.

This was a most important modification and the suture of chromicized catgut is to-day, I believe, with the possible exception of kangaroo tendon, the best suture for hernia operation. Shortly after 1890 silkworn gut was introduced as the ideal buried suture, and for a long time it was largely used in operation for hernia, especially in the United States. The advantages of kangaroo tendon, over catgut seem to have been first recognized by Dr. T. M. Girdlestone, a lecturer on surgery at the University of Melbourne. As early as 1877 he brought it to the notice of the Medical Society of Victoria, and in November, 1881, through Sir Thomas Smith of London, he addressed a communication to the Medico-Chirurgical Society of London. In this paper[1] he stated that the tendon suture resists the softening influence of the tissues much longer than catgut. He prepared it according to Lister's method of preparing catgut in carbolic oil, but also stated that if desired it could be furthered hardened by putting it in chromic acid one-half per-cent. solution for seven hours. It has been largely due to the writings of Marcy that it has come to be used so largely in operations for hernia. I have personally employed it in upward of 600 operations for hernia and I regard it as practically an ideal suture. The only difficulty has been in securing tendons of the proper size. If too large they remain in the tissues too long before absorption, and thus are open to the same objections that hold true of non-absorbable sutures. Split tendons should never be used as they are lacking in strength, and are of uneven caliber. Girdlestone himself in 1881 pointed out this fact. Some judgment is needed in selecting the proper size. I prefer for the deeper sutures a tendon equal in size to a No. 2 or No. 3 catgut, while a tendon the size of a No. 1 catgut, or even smaller, will suffice for the closure of the aponeurosis. The cost of the tendons and the difficulty of obtaining tendons of suitable size and strength are objections of some weight. I am not sure that a carefully prepared and properly chromicized cutgut will not prove nearly if not quite as good a suture for hernia as kangaroo tendon, and this is fortunate inasmuch as the supply of tendons is likely to prove insufficient to meet a largely increased demand.

The real and important objection to silk, silver wire, and the whole list of non-absorbable sutures,

[1] *Brit. Med. Jour.*, November 18, 1882.

[1] *Trans. of Medico-Chirurg. Soc.*, 1882.

remains to be noted, and is their liability to cause sinuses at long periods after operation. This objection is not theoretical but based upon personal observation of twenty-seven patients at the Hospital for Ruptured and Crippled, as well as upon numerous reports of other observers. In every one of these cases a sinus developed at periods varying from a few months to three years and eight months after operation. This condition of sinus formation is a serious one, inasmuch as the healing of the sinuses often requires many months and seldom become permanent until the last of the offending sutures has been removed. Nor is this the end, for the prolonged suppuration has in most cases so weakened the canal that relapse usually follows. Thus what might have been a successful operation for the radical cure of hernia has become a complete failure owing solely to the use of a non-absorbable suture. The reasons formerly advanced by surgeons for using non-absorbable sutures were that catgut could not be satisfactorily sterilized, but with our improved methods of sterilization such reasons no longer obtain. A comparison of the statistics as regards wound healing of the surgeons who use catgut and those who use non-absorbable sutures will disprove the validity of such claims.

Primary wound healing was obtained in but 80 per cent. of Halsted's series of cases in which silk was used for the buried sutures, and his later statistics of 261 cases in which silk, silver wire, and silkworm gut were used, 31 suppurated or 11 per cent. These patients, we must remember, were operated upon at a hospital which enjoyed a reputation above all others for the perfection of its aseptic technic. Yet the statistics of other surgeons, under much less favorable operative conditions, who have used absorbable buried sutures show better results as regards primary wound healing. I mention these facts simply to show that the claim, that non-absorbable sutures are necessary to obtain the best results in primary wound-healing, is entirely unfounded. Therefore, there is no logical reason why the final results of the operation should be jeopardized by their use.

With the vast improvement that has taken place during the past decade in methods and results of operations for radical cure, the indications for operation have markedly increased, though in some respects the present views as to selection of cases for operation differ materially from those held ten years ago. At that time operations were almost entirely confined to adults. This was due to the fact that some regarded the operation as more dangerous in children, and others believed that all ruptures in children could be cured by mechanical means. We now know that both these suppositions were erroneous. The results of large series of operations indicate that the operation is less dangerous in children than in adults; and furthermore a careful study of the after history of a large number of children with hernia has proved that at least one-third of such children pass on into adult life with the hernia uncured by mechanical means. This does not warrant us in advising operation in all cases of hernia in children. At the Hospital for Ruptured and Crippled in New York we have adopted the following rules in the selection of cases and it will be seen at once that these are fairly conservative: Operation is advised (1) in children over four years of age on whom a truss has been given a fair trial without marked improvement. (2) In cases complicated by fluid in the hernial sac (reducible hydrocele). (3) In all cases of femoral hernia, since this form of hernia offers little or no hope of cure through mechanical treatment.

The practice of operating upon infants under one year of age or even two or three years is, I believe, open to serious criticism. Umbilical hernia in infants and children should with some exceptions never be operated upon, for the reason that it is almost invariably cured by other means. With regard to adults it is not longer considered advisable to operate upon the very large and long irreducible herniæ in patients beyond middle life. The operation is attended with grave risks and a speedy return of the hernia will almost certainly occur. The same is true of the large irreducible umbilical hernia especially common in very stout women. While we cannot hope to cure such patients by operation, we should bear in mind that there has been a time when every one of these patients could have been operated upon with a fair prospect of success. Hence the importance of operating early.

Inasmuch as there is only slight prospect of a cure being effected by a truss after the age of twenty years, we can now advise operation in such cases, especially since it is no longer attended with appreciable risk, and the prospect of a permanent cure is very great. Operation should seldom be advised in patients over sixty years of age.

Inguinal hernia in the female has thus far received but little attention, and yet this variety of hernia yields the best results of all under operative treatment. Championnière was the first to urge operation in these cases, and he has recently reported forty-nine cases. His method was to excise the round ligament along with the sac, but I believe this to be, not without objection, and, moreover, entirely unnecessary. The sac can in every case be dissected free from the ligament with a little care and patience.

Kelly[1] of Baltimore transplants the round ligament exactly as Halsted transplants the cord in inguinal hernia in the male and closes the wound by Halsted's method. During the past eight years I have operated upon 100 females with inguinal hernia, and although the patients have been most carefully traced not a single relapse has been observed. The method employed is precisely similar to Bassini's operation in the male, with the transplantation of the cord omitted. The sac having been carefully dissected from the round ligament well beyond the internal ring, is tied off and excised. The round ligament is then allowed to drop down into the lower angle of the wound, and the wound is closed in two layers with buried sutures, according to Bassini's technic. The operation is much simpler than the one performed by Kelly, and the results thus far obtained are perfect.

Time will permit of but the briefest reference to the radical cure of femoral hernia. It is not generally recognized by the profession that the results of operation for femoral hernia are even more successful than for inguinal. Although a great variety of methods, many of them complex in technic and difficult to perform, have been proposed, the simple methods have been found to give the most satisfactory results. Bassini[2] has reported 54 patients operated upon by his own method, without mortality, and 41 of these were traced from one to nine years without a single relapse. Of my own cases, 40 in number, Bassini's method was employed in sixteen, and the method of high ligation and incision of the sac, with closure of the femoral canal by means of a purse-string suture of kangaroo tendons was used in the remainder. The single relapse observed occurred in a patient operated upon by Bassini's method, and it is worthy of note that this was the only case in which there was a failure to secure primary union.

It would not be right to close this brief and very imperfect sketch without saying a few words upon the final results of operations for hernia, in other words, upon the permanency of the cure. Do operations, even according to the best methods, and skillfully performed, really cure the patient, or is he only temporarily relieved? The answer to the question must as yet be more or less tentative. If by a permanent cure we mean freedom from relapse, as long as the patient lives, then, of course, the time has yet been too short for us to make dogmatic statements. Fortunately, however, we already possess sufficient data to enable us to draw fairly accurate conclusions. The careful study of 361 cases of relapse following various operations for inguinal and femoral hernia observed at the Hospital for Ruptured and Crippled during the past ten years shows the important fact that the great majority of relapses occur within the first few months after operation. Sixty-four and a half per cent. occurred during the first six months and 80 per cent. during the first year, between one and two years after operation 8.89 per cent. relapsed.

From these facts we are justified in concluding that in cases well beyond one year the chances of recurrence are very slight though in some cases relapse has been noted twenty years after operation. Under the methods practised a decade ago the percentages of relapses even during the first two years ranged between thirty and forty per cent. Under the improved method now in use, especially Bassini's, and even with a much more careful tracing of patients this percentage has been reduced to a minimum.

Such then at the dawn of the Twentieth Century is the present status of the radical cure of hernia. "The thousand-year old problem of surgery" has finally been solved in the last quarter of the Nineteenth Century by the happy combination of brilliant genius, rare skill, and unflagging perseverence on the part of many workers in many lands. We must not forget that this combination would have been of little avail without the brilliant discoveries of Morton and Lister. So, that here again in the radical cure of hernia, we find new cause to do them honor and to add to their laurels.

CEREBROSPINAL MENINGITIS.[1]

By JOSEPH W. IRWIN, M.D.,
OF LOUISVILLE, KY.;
PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN THE KENTUCKY SCHOOL OF MEDICINE.

SINCE 1874 three severe visitations and many sporadic cases of cerebrospinal meningitis have come to my notice. Every variety of the disease and its various complications and sequelæ were observed. Following the very cold winter of 1873 and 1874 the disease appeared in Evansville, Indiana, and vicinity. Children were most frequently its victims, and nearly all of those who were first taken sick died. The aged were rarely affected, but a few cases occurred in persons over sixty years of age, and they all died. The rate of deaths was more than 60 per cent., and nearly one-half of those who survived were left crippled mentally and physically and for them death would have been preferable to the miserable existence to which they were doomed.

[1] Read before the Louisville Clinical Society, June, 1899.

There were no prodromata. The disease came on suddenly with a chill or chilly sensation, and in young children convulsions often announced the attack Pain usually began in the back of the head low down, but sometimes it was first felt in front, or on top, or on one side. Very rarely was the pain complained of at the onset below the cervical region. Within a few hours, or one or two days, pain, usually lancinating and very severe, extended to the spine, arms, and legs, sometimes girdling the chest and abdomen. Vertigo and nausea were early symptoms, the latter often continuing for six or eight days.

Dimness of vision was sometimes complained of at the beginning of an attack, and this grew worse and partial or complete blindness ensued. Divergent strabismus of one or both eyes appeared in some cases within the first two days of the illness. The face wore a peculiar expression of suffering, sometimes a waxy pallor, and sometimes a purplish red with the eyes suffused. Fever was usually not severe, the temperature rarely reaching 103° F., and in some cases it was below the normal The pulse was slow as a rule, but in starts it would beat as high as 170 to the minute, and without any apparent cause the beats would become less frequent until 40 or 50 to the minute was recorded.

At first, in the moderately severe cases, the pulse was full and strong, but after the first day it became weak and irregular. Mental symptoms appeared early and often were more severe than other phenomena present would indicate. After a few hours or a few days the symptoms became more severe and the muscles of the back and neck were set in tonic contractions with the head thrown back beyond the perpendicular. On attempting to depress the chin the pain in the neck and back was increased. Opisthotonos was present in severe cases and was especially prominent in most of the fulminant variety. The head and feet would come within a few inches of touching each other. In the fulminant form of the disease death in from four to seventy-two hours was the invariable result. All the symptoms gave evidence of intense suffering from the beginning. The pulse recorded 200 at times, again falling below the normal, and the temperature rose to 106° or 107° F. The respiration was irregular and supracostal. Delirium was often wild, sometimes muttering, which ended in coma and death.

Purple-colored spots of various shapes and sizes appeared on the face, neck, body, and legs, which often disappeared suddenly, at times remaining three or four days. Now and then a case was observed in which the patient had a waxy, pale face, feeble, irregular pulse, 35 or 40 to the minute, and a subnormal temperature without opisthotonos or pain which deepened into coma and death in from four to eight hours. This form of the disease was very rarely seen. The disease in such cases seemed to be entirely confined to the brain. When death occurred within the first few hours autopsies revealed nothing of special significance beyond some patches of engorgement along the course of the blood-vessels, over the hemispheres, on the side, at the base, and about the medulla. The cord presented similar appearances though not so markedly as the brain. There was no serous exudation.

Another class of cases, in which the patients died after a week or two, showed more marked changes in the brain and cord The blood-vessels were hyperemic, inflamed, with deposits of lymph smeared over them and in various patches over the hemispheres, in the ventricles, at the base, in the canal, and about the cord. Effusions, serous or purulent, were found at the base, in the ventricles, and in the canal of the cord. Here and there the membranes were adherent to the brain, and numerous minute hemorrhages were observed. In another form of the disease, which was recurrent, the patient died after four or six weeks, or months, paralyzed and exhausted; and the autopsies revealed abscess and degeneration in the brain and cord.

The second epidemic of the disease was in 1877, and nothing different from the first was observed. A few cases of smallpox occurred at the same time. In both visitations croupous pneumonia preceded some cases, complicated others, and became a troublesome sequel in a few of those who survived the meningeal trouble. Pneumonia was present before, during or after the disease in one-fourth of all the cases I saw. In a few instances the cause of death was ascribed to it as it was the most serious feature of the illness.

When the clinical picture of the malady was made up neither the myocologist nor the ophthalmologist was a necessary factor in determing the diagnosis. A few cases only were observed in which there was any doubt as to the diagnosis, but after a day or two all doubts were removed. It would tax the powers of the most accurate observer to describe every detail of the objective symptoms even though sympathy with the sufferer had sharpened and rendered acute the workings of his special senses. But no great difficulty should be experienced in making a diagnosis when it is remembered that the disease is prevaling. In sporadic cases mistakes in diagnosis are more likely to occur. A person in good health, suddenly seized with pain in the head, over the hemispheres, on the side, or at the base, with pain in the back of the neck, along the spine, arms and

legs, sometimes girdling the chest and abdomen, with anxious look, a suffused eye, the face flushed or of a waxy palor, usually a slow pulse 40 to 60 to the minute, with or without fever, and with irregular respiration, may be regarded as having cerebrospinal meningitis. Then add to this the vertigo, the disturbed vision, the hyperesthesia, the sudden changes in temperature, the early delirium and the persistent nausea and vomiting and the diagnosis becomes more apparent. Kernig's sign will be present in all such cases. Since my attention was called to it a few years ago I have not found it absent in any case either of the sporadic or epidemic kind. There is no practical difference in the phenomena of sporadic and epidemic cerebrospinal meningitis. The same sort of bacilli have been found as the cause of each. Only in very exceptional cases will lumbar puncture be required to confirm the diagnosis.

The prognosis was always very uncertain. Even a mild case would take a turn for the worse or be so long protracted that death would result from exhaustion. A high temperature was always an unfavorable indication and it usually preceded death. Recurring cases were the most protracted, but the patients usually recovered, and when the first ten days of illness were past without serious complications recovery was more to be expected.

There was no time limit to the disease. Some patients were able to sit up and go about after two weeks, some after three to nine months, and others were not fully well after two or three years. Many of those who survived the acute part of the disease were left crippled mentally and physically for life. When it is remembered that the cerebrospinal centers are the seat of the disease any sort of complications or sequelæ may be expected to arise. Mental weaknesses were observed; some individuals were deaf, some were dumb, others were blind, and some were paralyzed. Suppuration of the ear and joints with swelling of the latter and contractures occurred.

In the treatment of cerebrospinal meningitis two important points were kept in view: one was an early diagnosis, and the other the free use or opium. Opium was the most useful in the forming stage of the disease, but it was more or less useful in all stages. It proved useful in relieving pain and preventing mental complications, perhaps by arresting serous effusions into the cavities and delicate textures of the brain, as in like manner it controls an intestinal diarrhea. Morphin alone was given hypodermically and the vomiting was often relieved by it, as well as the cerebral trouble. One-third or one-fourth of a grain, repeated at intervals of a few hours, was sufficient to afford relief. In fever the application of ice-bags to the head and spine was useful. Hot foot-baths were useful in equalizing the circulation when the extremities were cold. The bowels were kept open by the use of mild laxatives. The importance of maintaining the strength of the patient was kept in view and food and stimulants were given in moderate quantities from the beginning. When nausea prevented their administration by the mouth various mixtures of eggs, cream, and peptonoids were given by enemata. In the case of patients having a subnormal temperature the full bath, tepid or warm, the patient being allowed to lie in it for half an hour gave much relief. The bath was resorted to two or three times daily. Other remedies which gave temporary relief were phenacetin, phenalgin, kryofin, caffein and codein, but the old remedy, morphin, was the most useful.

Counter-irritants to the neck or spine proved to be useless. Sometimes the application of dry heat to the head and spine was soothing, hot bags of salt, hops, and water, and hot flannels were used. Laminectomy and spinal puncture for diagnostic and therapeutic purposes were not resorted to. Late in the course of the disease some benefit appeared to result from the use of small doses of bichlorid of mercury, one tenth of a grain, three times daily. Iodid of potash and syrup of the iodid of iron and quinin were employed with apparent benefit to the patient. Complications were treated as the indications arose.

Since 1879 numerous sporadic cases of cerebrospinal meningitis have come to my notice either as primary ailments or as secondary results. In acute cases I have found Kernig's sign of much value in making the diagnosis. Cerebrospinal meningitis, as it has recently prevailed in Louisville and throughout the State of Kentucky, has presented no new features. In some localities it has not been quite so fatal as in others. About 30 per cent. of the patients I have seen have died. In the southern part of Kentucky reports would indicate a death-rate of 80 or 85 per cent., with the usual percentage of mental and physical cripples remaining. The usual death-rate recorded is from 20 to 80 per cent.

Let us turn to a brief history of cerebrospinal meningitis, then view it in a clearer light of modern research, and some truths may appear to point the way to a better understanding of this dangerous malady. French writers claim that it was recognized early in the Christian era, but Hirsh by his careful investigations has shown that the claim is not well authenticated. The first accurate report of the disease was given by Viesseaux of Geneva, in 1805, when it prevailed in that city and in various parts of Switzerland. At intervals of a few years it appeared in various parts of Europe but England and

Scotland were the least visited. It spread through Germany, France, Spain, Italy, Denmark, Sweden, Norway, Holland, and Great Britain, especially Ireland, and was known in that country as the "black fever." The disease also appeared in Russia, in Turkey, in Greece, and in Asia Minor. It was first observed in the United States in 1806. It appeared at Medfield, Massachusetts, and soon spread westward to various States, North and South. It appeared at intervals in various cities, towns, and villages and in rural districts, sometimes not in the direct line of human commerce. No very serious epidemic has been recorded in the United States such as occurred in Sweden in 1854, when upward of 4000 deaths resulted from a single epidemic. The disease is said to be indigenous in Germany and it may be said that this is also true of parts of America. It has not been absent from Boston and Philadelphia for twenty-five years, about 6000 deaths have been ascribed to it in and about those cities within that period of time.

Cerebrospinal meningitis made its appearance in Kentucky during the last days of November, 1898, and soon after was observed in various parts of the State. The first case I saw in Louisville was about the middle of December, 1898. The disease had been reported in Boston, New York, and Philadelphia, and in numerous smaller cities and towns about the latter part of August of that year. It occurred in Baltimore and Richmond in October. It seemed to spread westward to various points, north, west, and south. The question of direct communication between infected and non-infected localities has not been clearly traced and the mode of communication from the sick to the well is still a mystery. The weight of evidence shows the disease to be infectious and even contagious, but the number of such cases is not great. The writer has seen five cases in one house, occurring in succession, three in another, and two in another. He is also aware of the case of a lady who came from a village in an adjoining State and remained with a sister for ten days who had meningitis, who, two or three days after returning to her home, was taken sick with the disease. A child contracted it from the mother and a few cases occurred here and there in the village. No case had been known in that locality before. Two nurses who cared for the sick were stricken.

These instances, which point to a direct infection, are few when viewed in the light of several hundred cases where only one occurred in each house. When it is remembered that there is no disease that affects everybody, and that the condition of the host is an important factor before the microbe enters, the few facts gain much force.

The recent discovery of the microbic origin of the disease must confirm the foregoing ideas of infection. Many forms of bacilli have been found in the meningeal exudates, but by far the most constant has been the micrococcus lanceolatus encapsulatus, either alone or with other bacilli. Lately the diplococcus intercellularis meningitidis has been found by numerous mycologists, Weichselbaum being the first to isolate it, in 1877. This bacillus is believed by many to be the cause of epidemic meningitis. All agree that the Freidlander bacillus will cause the disease in a very malignant form. The latter organism was first isolated by Eberth, in 1880. He found it in the cerebral exudates of a case of meningitis following pneumonia. Bozollo and Leyden found the pneumobacillus in 1883. Prudden found the Friedlander bacillus in a case of traumatic meningitis. Netter found the pneumobacillus in sixteen out of thirty cases of meningitis in which pneumonia had not occurred. He also found the micrococcus lanceolatus encapsulatus in the mouths of 80 per cent. of healthy people examined. Pneumonia and meningitis are so frequently associated that Fagge of Erlangen has reported fourteen such cases that came to his knowledge between 1866 and 1872.

In the report of the Board of Health of the State of Massachusetts for 1898 Drs. Councilman, Mallory, and Wright seem to have found in the exudates of cerebrospinal meningitis the diplococcus intercellularis most frequently. In cases in which lumbar puncture was practised within the first ten days of the attack it was nearly always present in the fluid drawn off but later it was not found so frequently.

THE TREATMENT OF TUBERCULOSIS.

By LAWRENCE F. FLICK, M.D.,
OF PHILADELPHIA, PA.

Sufficient progress has been made in the treatment of tuberculosis during the last decade to warrant the removal of the disease from the category of incurable to that of curable diseases. By this is not merely meant that certain patients recovered from tuberculosis, as has been demonstrated on the autopsy-table, but that the power of the physician over the disease has been increased to such an extent as to enable him to cure a fair number of patients and to stay the progress of the disease when he cannot cure. These results have been attained, not by the discovery of specifics, but by the acquisition of a fuller knowledge of the etiology and pathology of the disease, of a better understanding of immunity and nutrition, and of a more exact knowledge of the action of drugs. Unfortunately this progress has not been sufficiently taken account of by the general

practitioner, who still but too often contents himself with smoothing the downward path of his consumptive patient to an inevitable doom with the prescription of cough mixtures and the recommendation of a change of climate.

With tuberculosis, as with everything else in the healing art, success depends more upon attention to details than upon the use of wonderful remedies. The man who has command of the largest number of hygienic, dietetic, and therapeutic resources, and who knows how to use them to the best advantage scores the largest number of successes. Measures which give excellent results in one case may not do so in another and may not do so in the same case in all stages. Hence adaptation of measures to an individual case and ready command of new measures when remedies which have done well no longer answer is of great importance. Sometimes a slight change in the diet or even in the dosage of a remedy will make a change for the better.

Immunity is the fundamental principle underlying the treatment of tuberculosis. Whatever makes for immunity makes for recovery. The chief means at our command for attaining immunity are: first, nutrition; second, drugs; and third, antitoxins. Nutrition must be assigned first place by all odds. For the attainment of nutrition we have forced feeding, artificial digestion, rest, exercise, and climate. By forced feeding is meant the taking in of a very large quantity of easily digested and readily assimilated food. In practising forced feeding care should be exercised to adapt the food to the individual and to inquire with the minutest detail into the patient's habits of eating and his capacity for digesting food. What agrees with one often disagrees with another. The best criterion as to whether the right food and the proper amount is taken is to be found in the patient's weight. If he is gaining in weight it may be assumed that he is getting the proper food and in proper quantities. When the stomach is incompetent to do its work, or when the secretions of the salivary glands or of the pancreas are deficient artificial digestion should be resorted to. Albuminous food may be predigested or pepsin and hydrochloric acid may be administered after meals to aid the stomach in digesting such food.

The digestion of starchy food may be aided by the administration of diastase in some form. All the organs concerned in digestion and nutrition should be carefully watched and kept up to their full standard of activity. In this connection the liver, intestines, and kidneys should not be lost sight of. The bowels should be kept open and the kidneys protected against overwork. And it must not be forgotten that oxidation is an important stage of the nutritive process. A liberal air-supply is as essential to healthy nutrition as ample good food, competent digestion, and assimilation and proper elimination. Life in the open air should, therefore, be pursued as far as practicable. The living and sleeping-rooms, when house-life is followed, should always be well ventilated. It does not make as much difference from whence the air is obtained as that the air be free from the products of combustion given off in respiration. Rebreathed air above all should be avoided. The old prejudice against night air, city air, and sea air may safely be laid aside. Of course country air is better than city air because it is freer from impurities of various kinds, but for the purposes of nutrition, city air, if it is obtained from out of doors, answers very well. Only let the consumptive have lots of it both by day and by night. A good plan is to allow him to lie out of doors in a hammock, well clothed and wrapped. If he cannot lie out of doors the recumbent position in a room with windows open is next to be preferred. A draught of air need not be feared provided the patient is properly protected with wraps. But outdoor life must not be interpreted to mean constant exercise. There is great danger in over-exertion. During activity of the disease as manifested by fever and acceleration of heart-action better results can be obtained from rest than from any other measure. In proportion as the active symptoms disappear rest may be supplanted, first by passive exercise, and then gradually by active and then more active exercise, until finally the patient may be allowed to do a hard day's work. When the circulation has resumed its normal course exercise becomes a useful means for the furtherance of nutrition. It should, however, be used under the direction of a physician.

Climate no longer plays as important a part in the treatment of tuberculosis as it did a few years ago. We know now that it is not so much the climate as the outdoor life that makes our patients do better when they go to the mountains. The idea that certain climates have a specific influence over tuberculosis was born of a misapprehension. Because certain regions which had not yet been infected were free from consumption the profession jumped at the conclusion that there was something in the climate of those regions which militated against the disease. Those regions have all become more or less infected and we now know that there is very little in climate itself that will ward off or cure consumption. During the acute stage of tuberculosis better results can be obtained at home, even if that home be in a densely populated city, than away from home, unless the patient can be placed in a well-equipped sanatorium. The mod-

ern sanatorium undoubtedly offers the best chance of recovery to the consumptive; but outside of a sanatorium, in acute cases, the chances of recovery are better at home than away from home. After acute symptoms have passed excellent results may be obtained by a change of climate, and then a climate should be selected to suit the idiosyncrasies of the patient. Persons with weak hearts do better at a low elevation than at a high one and sometimes do best at sea-level, and preferably at the seashore or on the ocean. Persons of vigorous circulation or of nervous or lymphatic temperament usually do better in an elevated climate. It is, however, not always a good plan to keep a patient in the same climate too long as there is some benefit to be derived from a change irrespective of what there may be in the climate itself.

What can be accomplished by drugs in the treatment of tuberculosis? A great deal if the drugs are judiciously used. We have no specifics for tuberculosis and may never get any, but we have valuable adjuvants and are constantly adding new ones to the list. In my own experience I have found iodin the the most valuable remedy at our command. I use it in the form of europhen, which I introduce by inunction. The following is the formula which I employ: Europhen, ʒ i; oil of rose, *m.*j; oil of anise, ʒ i, and olive-oil, ʒ iiss. Of this I have the patient rub from a teaspoonful to a tablespoonful into the armpits and into the inside of the thighs once or twice a day. Formerly I used iodoform in this way but owing to its offensive odor I have discarded it in favor of europhen, which is even richer in iodin than iodoform. As the patient becomes more tolerant of the iodin I sometimes reinforce the inunctions by giving the europhen by the mouth in addition. I have tested the value of this treatment for a long enough period to convince me that it is real and worthy of confidence. The treatment ought to be kept up for a long time and even after all symptoms of the disease have disappeared.

The next most valuable drug in my experience is creosote. This is of especial value in the more advanced stages of the disease. In all cases of tuberculosis which have advanced to the stage of breaking down I give creosote in addition to europhen inunctions as a routine treatment. In order to get the full benefit of creosote large doses should be given. I begin with 1 drop and increase the dose gradually until the patient takes from 40 to 50 drops three times a day. The best vehicle which I have found for administering the drug is hot water. As I increase the dose of creosote I increase the amount of hot water, and in this way my patients find themselves able to take large doses of the drug without inconvenience. The maximum dose is usually taken in a pint of water. As a rule I order the creosote taken before meals and am under the impression that it stimulates the appetite. I use pure beechwood creosote in preference to other preparations because it is less expensive.

The third place in the order of importance in the value of drugs for the treatment of tuberculosis I unhesitatingly assign to strychnin. In what way it acts I do not know, but if given in proper doses it helps to increase weight and improves the heart-action. As a rule it ought to be given in large doses, but all patients do not bear large doses well. The dose should be changed from time to time. Other drugs that are useful in properly selected cases are arsenic, digitalis, mercury, both in the form of calomel and corrosive sublimate, belladonna, muriate of ammonia, aromatic spirits of ammonia, nitroglycerin, the mineral acids, and the vegetable tonics. Most of these drugs may be used to advantage for building up nutrition. Nitroglycerin is useful for checking hemorrhage, ammonia for stimulating the secretions of the bronchial glands.

Antitoxins in the treatment of tuberculosis are still on trial and for self-evident reasons cannot be judged for some time to come. Of the men who have used them in various forms and modifications the most conservative speak guardedly of their value. There is undoubtedly some merit in them and they seem to be legitimate remedies in the hands of competent persons. The tuberculins, antituberculins, serums, and nucleins may all be grouped under the head of antitoxins as they all probably act in the same way. I have as yet had no experience with any of these preparations, but for some time I have used a modification of antitoxin treatment, if I may so call it, which has given good results. I place an ordinary fly-blister over the affected lung, front or back, and allow it to remain in place about an hour. I then have the plaster removed and the skin washed with warm water. In the course of a few hours a large vesicle will rise and as the epidermis has not been broken the serum is retained and in twenty-four hours is reabsorbed. During the process of resorption of the serum chills, malaise, and some fever are liable to occur and the whole picture of the clinical symptoms is similar to that which has been described as occurring after the injection of antituberculin. For the occurrence of these phenomena I have only the word of patients, as I have not had an opportunity of making careful bedside observations. I believe I can safely say, however, that benefit follows the application of a blister in this way, and that the benefit is greater than that which ordinarily follows the application of a blister.

EMPYEMA FROM A SURGICAL STANDPOINT.[1]

BY JOHN C. MUNRO, M.D.,
OF BOSTON, MASS.;
ASSISTANT VISITING SURGEON TO THE BOSTON CITY HOSPITAL; INSTRUCTOR IN SURGERY IN THE HARVARD MEDICAL SCHOOL.

I HAVE very little that is new to add to a subject upon which so much has been written, but there are a few points that I think will bear repeated emphasis until it is more thoroughly recognized that pus in the pleural cavity needs as early and complete evacuation as it does when in the abdominal cavity. My conclusions are drawn entirely from my own experience and they have been reached after much thought and observation.

Anesthesia.—In the hands of a skilled etherizer there are very few cases in adults, to which class my experience has been largely limited, in which ether cannot be given; but unless properly given and with intelligent supervision of each inspiration it may be dangerous. It can be given to children easily controlled, while in very young children the stage of unconsciousness is so rapidly attained that its use is safe in a large majority of cases. The rule of giving fresh ether or fresh air, avoiding asphyxiation, must always be observed. I have seen collapse from ether in an infant in one case, but in this instance, and probably in similar cases, the operation had been so long delayed that anything beyond aspiration would have produced collapse. I have used chloroform in double empyema in children, and when struggling and coughing had to be reduced to the minimum. In adults, however, with whom one can reason, I believe that ether is safe and preferable in a large proportion of cases. I have used it without evoking any symptoms to cause anxiety in patients with deep cyanosis, delirium, muscular twitching, intermittent pulse, and excessively rapid respiration; in a woman, seven-months pregnant, with deep cyanosis and a weak, rapid pulse; in a man with the left chest so full of pus that the spleen was pushed down to the ilium and so distressed in his breathing that he could not lie down. On the other hand, in one case, a man profoundly poisoned with streptococcic absorption, ether was taken badly, the stage of excitement was marked, and undoubtedly in this instance the operation should have been performed under local anesthesia, but such a case is rare. The objection to the use of cocain as a routine means of producing anesthesia is the mental shock and fright added to the peculiar condition of mental distress that is so characteristic of this disease; the struggling which is frequently more marked than in patients properly etherized, and the not infrequent imperfect anesthesia produced. The struggling that attends primary anesthesia with ether is easily controlled, is of short duration, and is not due to suffering.

Expansion of the Lung.—To insure rapid expansion of the lung too much cannot be said to induce physicians to submit their patients to early operation. Were this principle followed more strictly than it is such operations as those devised by Schede and Estlander would rarely be required. One cannot tell beforehand in what type of case the lung will expand early, and although occasionally a patient is seen in whom, after conservative treatment, rapid expansion follows a late operation, these cases are exceptional and are dangerous precedents. To have the compressed lung follow one's finger to complete expansion as the pus flows from the chest is most satisfactory both to patient and surgeon, while to submit a patient after months or years of treatment for a persistent sinus to a severe operation, a long convalescence, and a deformed and inadequate chest is disheartening to say the least. I have doubts of one's ability to foretell what lung will expand rapidly in all cases. Of two adults with streptococcic empyema following pneumonia, operated upon within a few days after the onset of the empyema, when the conditions were as nearly alike as possible, the lung in the one case followed the evacuation of the pus and expanded to completion at once, while in the other the lung refused to expand to any extent by the end of a week, when death took place from a pneumonia of the opposite lung. In another streptococcic case treated expectantly for two months the lung steadily expanded, in a few weeks after resection of a rib, but this is an exceptional case and an unsafe example to follow. I have had delayed expansion or incomplete permanent expansion in both pneumococcic and streptococcic empyema, but when the operation has been done soon after the formation of pus immediate expansion has taken place in both types, though as a rule complete expansion is rather apt to be slower in the pneumococcic cases, that is, full resonance is not noted before several weeks. The cases of incomplete expansion in which operation has been delayed are usually those of mixed infection, and the severer secondary operations have been resorted to after long and tedious drainage.

It is a well-established rule that pus should be evacuated as soon as it is discovered, and yet I know of no place where this principle is more applicable than in cases with pus in the pleura, a principle that in my experience is constantly violated by practitioners of large experience.

It should be borne in mind also that incomplete expansion may come from imperfect drainage, from relapse consequent upon a return to a life of hard-

[1] Read at the sixteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

ship or dissipation too soon after healing of the wound, and from an accident that occasionally happens, the loss, unknown to patient and surgeon, of a drainage-tube or a sponge in the pleural cavity.

The sinuses that persist in tuberculous patients form a class by themselves and are not considered here.

Cause of Death.—The deaths in my cases have come from dislodgment of an embolus from hearts displaced by a left pleural cavity filled with pus; from a relapse or an extension of a pneumonia, and in the streptococcic cases from a rapid general infection. In the first class of cases, especially of long standing, one or more preliminary aspirations to reduce the distention gradually are safer, but in recent cases it seems sufficient to evacuate slowly at the operation and then to enforce absolute rest for a few days. The streptococcic cases occasionally are so rapidly fatal that, no matter how early the cavity is emptied, nothing is of avail; but in those not so acutely poisoned, when there is a steady and persistent absorption, the chances of recovery are far less after a late than after an early operation, and this possibility is very apt to be overlooked by those who have had but little experience in pyemia and septicemia.

Technic.—The operation for empyema is well described in all text-books, but I wish to suggest some modifications that have proved useful to myself and which may be of some help to the practitioner who is called upon but rarely to undertake the operation.

I make it a rule to explore with a trocar for diagnosis as soon as the patient is anesthetized. In old left-sided cases, with marked displacement of the heart, the pus may be withdrawn by preliminary aspiration to avoid the risk of embolism. I rarely open between the ribs; drainage is not so satisfactory and, unless there are urgent indications to the contrary, resection of a rib is practically as safe, and in other ways is better surgically in the large majority of cases.

The incision, especially in cases requiring rapid operation under primary anesthesia, is best made at a right angle to the rib. There is no danger of missing the rib selected; it can be reached at one stroke, and plenty of room is allowed for resection. Practically I now use this incision in all cases. It is not necessary to resect the rib at the lowest level. Personally I prefer the seventh or eighth; the cavity usually found is just as well drained at this level and there is no danger of wounding the diaphragm.

In cleaning the periosteum from the rib I prefer a periosteum elevator without a cutting edge—the handle of a knife or a pair of scissors curved on the flat is equally good—because the danger and annoyance of wounding the artery is reduced to a minimum.

The cavity drains equally as well if made in the anterior or mid-axillary line as when made far back where the rib is more difficult of access. The drainage-tube should be short; it should not project beyond the inner surface of the chest. The cavity drains better and the irritation of the lung pressing on the end of a long tube is obviated.

When a suitable operating-table is at hand the operation may be done with the patient half sitting up, the arm of the affected side being held over the head. In this position free respiration is allowed to the healthy side and free access is given to all but the furthermost portion of the chest posteriorly. Moreover, most patients breathe more easily in this position.

After operation patients improve more rapidly if they are allowed to sit up as soon as they can do so safely. Systematic lung and chest exercises, climbing hills, running, etc., are all valuable aids in expanding the lungs. The pneumatic cabinet, and in obstinate cases, removal to a high altitude should be of value also, though I have had no experience to verify the latter suggestions.

CLINICAL MEMORANDUM.

A CASE OF SARCOMA OF THE TONSIL. THREE REMOVALS, RECURRENCE AFTER EACH. DEATH FROM METASTASES IN MESENTERY AND BOWEL.[1]

J. MORRISON RAY, M.D.,
OF LOUISVILLE, KY.

Sarcoma of the tonsil has been looked upon as a rare condition, this view being largely due to the statements found in the text-books of McKenzie and Bosworth. The former under the general head of cancer of the tonsil remarks that the disease is rare; yet later, in the same chapter, states that lymphomata, or lymphosarcoma are found as a part of a general condition. Bosworth could find in 1892 only 45 cases that could be considered as having their origin in the tissues of the tonsil.

In 1895 Lamphear found 71 cases recorded. Since then it has not been uncommon to see isolated cases reported. Very few surgeons have seen more than 1 or 2 cases in a long and extensive experience.

I wish to report a case that in many respects is unique: W. H. H., aged thirty-seven years, consulted me May 7, 1898, with the following history: For two months he had noticed a small mass forming in his throat on the left side. No pain or other discomfort until the past few

[1] Presented to the American Laryngological, Rhinological, and Otological Society at its annual meeting, May, 1899, Cincinnati, Ohio.

days, when it began to be sore and present a sense of something in the throat, and seemed to interfere with talking by the presence of a fulness. He had been in poor health for several months, had lost flesh, and said he had dyspepsia. His family history was negative. On examination, I found on the left side, hanging by a narrow pedicle from a crypt of the tonsil at its lower part, close to the anterior pillar, a mass as large as an olive of a dark purplish color, and roughened on its surface like a raspberry. It could be lifted by forceps, and the pedicle was well defined. There was no cervical glandular enlargement. The appearance was suggestive of papilloma and I advised removal by means of the snare because of the apparent great vascularity.

The tonsils on both sides had undergone the normal atrophic process, and did not protrude beyond the plane of the anterior pillar. He had not been a sufferer from chronic throat trouble or recurring tonsillar inflammation.

The parts were cocainized and a cold wire snare loop was easily passed around and pushed well down on the pedicle. The growth seemed soft and yielded easily to the snare constriction. In ten minutes the mass came away. Only a little blood-stained saliva was expectorated. The mass was examined closely after removal and macroscopically looked like an angioma, numerous small blood-vessels being seen just beneath the epithelium. No discomfort followed and he was not seen again for three days. At that visit a small granulating mass seemed to be pouting from the tonsil crypt but nothing was done, as it was believed that it would rapidly cicatrize.

June 20th I next saw the patient; he said the mass in his throat was growing again. On examination I found that it was returning, and was then as large as a raspberry, and resembled it very much in size, color, and conformation, attached to the tonsil by a constricted base somewhat broader than the original pedicle. This second growth was removed with Gradle's cautery snare close to the tonsil, and the depression from which it sprung was gone over thoroughly with a cautery-point, and the parts thoroughly destroyed. I saw him in two days, the throat being quite sore from the burning. Being now suspicious of the condition, I asked my friend Dr. A. O. Pfingst to examine the mass removed. His report is as follows:

"I take the specimen you sent me for a lymphosarcoma. It was soft to the touch, had an uneven surface covered by a smooth membrane which in parts was thick and formed white nodules. The membrane otherwise was thin and transparent, showing the brown tissues beneath it. It was easily torn or punctured by a slight touch of a blunt instrument. On the interior the mass had a brown color. It was soft and brittle and could readily be made to bleed. Particles of the tissue, teased in glycerine, showed large, round cells with granular protoplasm and many red blood-cells, also some fibers of connective tissue.

"The specimen was hardened in formol, sections being made through its long diameter and these stained with hematoxylin and eosin. The growth was covered externally by stratified epithelium, a light line of demarkation being visible between it and the pseudoplasm. The tumor mass was made up almost entirely of large, round cells with nuclei loosely arranged and separated by a granular intercellular substance.

"Bands of connective tissue could be seen distributed throughout the tissue, many of them carrying wide blood-vessels. Extravasated blood could be seen abundantly throughout the tissue in areas of different sizes."

I next saw the patient July 24, 1898. He informed me that since the last operation he had been suffering from his stomach and bowels, and had spent two weeks at a resort the waters of which had been advised for this bowel trouble. During the last two weeks the throat tumor had again begun to show itself, and that a small lump that felt tender on pressure could be felt on the outside. I now informed him of the possibility of the serious nature of the growth, and advised its removal more thoroughly. On examination I found the recurrence was not extensive and the surrounding parts were not inflamed. For the third time the growth was removed, the cautery snare being used and the entire tonsil deep between the pillars cauterized. Four days later I saw him, the cauterized area was clearing of slough and looked well, but the glands along the margin of the sternomastoid were tender and several of them enlarged.

For the further history of the case I am indebted to Dr. James B. Bullitt. September 17, 1898, the patient was seen by Drs. Cartledge and Bullitt with the history that two weeks before he had noticed a lump in the left side below the ribs, about the size of a turkey egg and movable. When seen he was suffering from evidences of acute bowel obstruction; an operation was done. The abdomen was opened in the middle line. The bowel was found obstructed by a nodular mass in the wall of the gut; intestines were much distended above. The mesenteric glands were enlarged, many being as large as a partridge egg. These enlargements in the mesentery were numerous along the vertebral column on the left side; two were removed. The patient died September 26, 1898, nine days after the operation. Microscopical examination of the mesenteric gland removed by Dr. Bullitt, showed it to be a round-celled sarcoma. The condition found at the operation was suspected, but as the symptoms of bowel obstruction were acute, the necessity of relieving this by abdominal section was urgent. The bowel was opened above the seat of obstruction, and water taken by the mouth in a short time passed through the incision, showing the opening in the small intestine to be high up.

Out of approximately 80 cases of which I can find records in the literature at my command, there are only 3 that in their local appearance and history seem to resemble the one just reported. Czerny reports a case of male, thirty-four, tumor pedunculated. Removal, recurrence, metastasis to wall of intestines, peritoneum, and mesenteric glands. Schroeller reports a case in which it assumed a well-defined pedunculated form. Charnley, 1895, reports a case of lymphosarcoma, the size of a small orange, removed three times, with rapid recurrence; original tumor had a very narrow, restricted pedicle. Knight states that the usual form of pedunculated tumor

growing from the tonsil is papillomatous, or fibromatous, usually the former. Schmidt among 32,997 cases of diseases of the upper respiratory passages found only 2 cases of sarcoma in this region.

Most of the cases that I find reported commence with enlargement of the tonsillar gland structure, and with evidences of local inflammatory action and discomfort. Lymphosarcoma, the most malignant variety, is the one most apt to be found originating in the glandular structure of the tonsil.

From the frequent and early appearance of gland enlargements in other parts of the body, especially the cervical region, it has been suggested that possibly the tonsillar condition was only a part of a general sarcomatous process, so-called Hodgkin's disease. When first noted in the tonsil metastatic deposits have been observed in the lungs, liver, intestinal walls, peritoneum, and mesenteric glands. The probability of it being a part of a general sarcomatous condition is borne out by the treatment; extirpation of lymphosarcoma either by external incision or by the mouth has not succeeded in prolonging life, recurrence and death taking place in from four to six months. The only cases in which recurrence has not been noticed were cases of spindle-celled growths.

MEDICAL PROGRESS.

Two Cases of Typhoid without Intestinal Lesions.—LARTIGAU (*N. Y. Med. Jour.*, July 23, 1899) reports two cases of typhoid fever, confirmed by autopsy, in which there were no intestinal lesions. The large and small intestines appeared at autopsy absolutely normal, and the retroperitoneal and mesenteric glands were not swollen. Cultures made from the liver, gall-bladder, and kidney contained bacilli which various tests showed to be the bacillus of typhoid fever. Only a few cases of this character have been reported.

The Bad Effects of Hydrogen Dioxid.—SPENCER (*Therapeutic Gazette*, July, 1899) mentions a number of cases in which the use of hydrogen dioxid has retarded the healing of a wound. In one of these the daily use of this agent for four days enlarged the sinuses in the breast, and was the means of carrying the infection beneath the axillary scar. The patient had been operated upon for carcinoma. In another instance a patient with two stitch abscesses in the abdominal wall suffered from cellulitis of the whole right side of the abdomen following immediately upon the use of dioxid of hydrogen. The bad effects are attributed by Spencer to the forcible dissemination of infectious material by the bubbling of the dioxid. The mechanical action exerted upon the tissues by this agent, during effervescence, is far greater than is supposed by many to be the case. It possesses the power to travel in relaxed tissues, along nerves, in the tendon-sheaths, and in the planes of the muscles. For this reason it is unsafe to use it in infected wounds in certain locations, with or without pus, in abscess cavities either acute or chronic where the walls are supposed to be weak, in closed cavities, and in the tissues surrounding the larynx and trachea, especially in young children.

Sterilization of the Skin.—SENGER (*Archiv für Klin. Chir.*, vol. 59, p. 425) gives the results of a long series of experiments conducted by him in order to discover the best method of sterilizing the skin. He finally adopted the following technic: (1) Mechanical cleansing of the skin with ordinary soap and water just as hot as it can be borne—about 40° to 45° C. (104° to 113° F.). This scrubbing should last at least five minutes. (2) Bathing or rubbing the hands with alcohol (forty to sixty per cent.). (3) Washing the skin for two minutes with a warm two- to five-per-cent. solution of hydrochloric acid. (4) Washing the skin for one minute with a warm one-half-per-cent. solution of permanganate of potash. (5) Washing the skin with sulphurous acid until it is decolorized. The whole process takes about ten minutes. Senger insists upon having the solutions warm, claiming that their antiseptic action is much increased by the heat. By this method he has been able to obtain sterility in almost every instance in which the skin was tested by scraping. He objects to this method of making the test, however, on the ground that it is not as accurate as when small snips of the skin are embedded in the culture material. When tested in this way the skin was found to be sterile in about seventy-five per cent. of the recent experiments. This is far in advance of the results he was able to obtain by any other method.

Importance of an Early Diagnosis in Melancholia.—BURNETT (*Kansas City Med. Record*, July, 1899) insists upon the importance of making a diagnosis in the incipient form of melancholia. He thoroughly believes that in nearly every case which is recognized early the patient may be cured by suitable treatment. Two striking histories in support of this view are given. Since January last the author has been called upon to treat nine cases of melancholia, all presenting apparently equal chances for recovery. Three of them were sent to a public asylum, where they still remain mentally unimproved. The other six were treated in a private institution, and every one has returned home apparently quite well, although the writer recognizes that a repetition of the wear and tear which caused the first mental break-down may bring on a second attack.

Complete Obstruction of the Bowel.—FELL (*Indian Medical Record*, June 14, 1899) reports a case of total obstruction of the bowel lasting thirty-four days. The patient had cancer of the sigmoid flexure, and had entered the hospital for operation, but, learning that a cure of his trouble would probably not be brought about, he refused all operative interference and returned home. For some weeks previous he had taken very little nourishment. After the obstruction became absolute he suffered intense pain for a few days, and had severe vomiting of greenish fluid containing material like coffee-grounds. Not even flatus passed his rectum. After the first week the pain was less, and at times he was free from vomiting. The patient washed his mouth with

water, and occasionally drank a little water, also a little ginger beer. In the second week the dark stains which one is accustomed to see on the cadaver began to show on the distended abdomen. These increased until at the end of a fortnight, the whole abdomen and thorax were mottled like the dependent portions of a corpse. An abscess appeared at the angle of the jaw on the right side, about the size of an orange; it suppurated and broke, and continued to discharge until the time of the patient's death. The urine was clear and free from albumin, and of 1023 specific gravity. The patient never complained of hunger. Up to the time of his death his mind was clear, and he gave as little trouble as possible. The pulse reached 110 by the end of the month, and gradually decreased to 80. About the twenty-fourth day of starvation the lividity began to spread to his arms, and by the thirtieth it was universal except for the face. He died on the thirty-fourth day. At autopsy the bowel above the obstruction was found to measure eighteen inches in circumference. It contained some liquid feces and an enormous quantity of flatus. The stomach and small intestine were empty. From his observations in this remarkable case, Fell concludes that people suddenly deprived of food, whether shut up in a mine or shipwrecked, and who die in from five to eight days, succumb from mental exhaustion rather than from actual starvation. In his opinion, if they would face their position with the fortitude which this man exhibited they might survive a month or more.

Intestinal Disturbances Produced by Otitis Media in Infants.—HARTMANN (*Archives of Otology*, April–June, 1899) has some years insisted that otitis media of infants may be accompanied by disturbances of nutrition, as evidenced by dyspepsia and emaciation. Upon evacuation of the contents of the middle ear by paracentesis the disturbances in digestion disappear, and an increase of weight follows. Elevations of temperature occurring in the course of intestinal disturbances may be referred to a complication with otitis. In all intestinal affections of infants, accompanied by elevation of temperature and reduction in weight, an examination of the ears for the possible presence of otitis should not be neglected. In adults chronic otitis often affects the general organism, and it is safe to assume that the same relation exists in the young infant. From a recent study of numerous cases he further concludes that acute febrile otitis causes a diminution in weight, or arrest of increase in weight; that otitis accompanied by grave septic symptoms probably causes diarrhea; that an acute febrile otitis occurring during intestinal diseases may act upon the general constitution, and by reducing the vitality, aggravate the intestinal affection or retard recovery; and that whether there is a direct relation between atrophy and an otitis, must be reserved for further observations.

The diagnosis of otitis media in young infants can usually be made by direct examination. Although the canal is small and obliquely situated, if the scales of wax which it contains are removed, preferably without syringing, the tympanic membrane can usually be seen through a suitable speculum. Frequently the examination appears to reveal a normal drum membrane. More importance should be attached to the opacity of the membrane, as an exudate may be present without causing it to bulge outward. In doubtful cases an exploratory puncture may be permissible. The treatment of otitis in infants is based upon the same principles as the treatment of otitis in adults. If there is restlessness, pain, fever, and emaciation paracentesis should be performed without delay. After the exudate which runs out of the opening has been wiped away, inflation should be performed and repeated daily. A bit of sterile medicated gauze should be kept in the auditory canal. If the chief symptom is pain, a warm solution composed of one part of carbolic acid to ten parts of glycerin may be poured into the auditory canal and pressed toward the tympanum by repeatedly compressing the tragus with the finger. After a few minutes the solution should be removed with absorbent cotton. Such attempts may be successful in cutting short the inflammation, and so avoiding paracentesis. If there are no urgent symptoms expectant treatment is advisable. If resolution does not take place spontaneously paracentesis should not be delayed. If the secretion is copious and purulent particular care should be taken to maintain a sufficiently large opening in the membrane. The mastoid cells may be involved. If so, their exudate drains through the tympanic cavity, but recovery may still take place without recourse to opening of the mastoid. Inflations of boric acid aid recovery, and as the powder is dissolved by the exudate there is little danger of retention. If the secretion does not diminish in spite of treatment, or if there should be edema or an abscess in the region of the mastoid, operation is absolutely indicated. One frequently finds granulations and detached particles of bone or even large sequestra. The general condition of the little patient must not be neglected. Nasal respiration should be maintained if possible. It is often helpful in nasal catarrh to close the mouth of the screaming infant, thus forcing it to breathe through its nose. If the nasal secretion is very purulent, a one or two-per-cent. saline solution or a weak solution of peroxid of hydrogen may be forced into one nostril while the head of the infant is held downward. Favorable results have also been obtained by the use of a 1 to 1000 nitrate-of-silver spray. The presence of adenoid vegetations in infants is a rare complication.

THERAPEUTIC NOTES.

On the Treatment of Rectal Prolapse.—LUDLOFF (*Archiv für Klin. Chir.*, vol. 59, p. 447) emphasizes the importance of a correct understanding of the structures in the rectal region if one hopes to treat intelligently a rectal prolapse. The rectum is not merely a mucus-lined tube, but a hollow muscular organ which, when it contracts, grows stiff and less movable. This contraction takes place synchronously with abdominal pressure. In normal individuals the whole rectal region is padded with abundant fatty tissue. The nor-

mal peritoneal cul-de-sac has a certain amount of consistence which prevents too great excursions. In patients suffering from prolapse this normal resistence of the different tissues is decreased and the position of the rectum may be altered. Ludloff has studied 111 cases of prolapse. He separated the patients affected into three groups. In the first are adults in the prime of life, nearly all of whom have worked hard. Many of them suffered for years from chronic constipation; others gave a history of typhoid fever or dysentery. They were usually thin, so that the padding of fat was deficient, while the muscular structure of the rectum was weak, and afforded too little resistance to abdominal pressure. Many of them had been in the habit of going regularly in the morning to stool whether they felt the desire for it or not, and of straining violently to accomplish their purpose. In a second group were women either at a period when they were bearing most of their children or at the age of menopause—in other words, at one of those periods in which hernia is most common. The individuals of the third group were children who had suffered from chronic catarrh of the intestine leading to atrophy of the muscles of the rectum and to an excessive abdominal pressure. Heredity plays no small part in the etiology of this trouble. Prolapse of the rectum is a species of hernia in which the peritoneum in front of the rectum presses down further and further, and finally appears, carrying the rectum before it, through the anal opening. It differs from other herniæ simply in the fact that its posterior wall is formed by the rectum itself, the normal supports of the latter having been gradually weakened. Treatment by operation has had a considerable mortality, and has often been followed by recurrence of the trouble because the hernial nature of the affection has not been recognized. For a prolapse which cannot be replaced, whether of the anus or of the rectum, the writer recommends that for two weeks attempts should be made to cure the trouble by massage according to the principles laid down by Thure Brandt. If no improvement takes place in this time anterior colopexy should be performed. If this is without success the rectum should be resected in the manner described by Mikulicz. *Prolapsus coli invaginati* should be treated according to the principles of invagination of the intestines. If the invagination is situated high up, laparotomy and the Barker-Rydygier operation should be performed. If the invagination is situated low down, a resection according to Mikulicz is indicated. Prolapse of the anus is a rolling outward of the mucous membrane, and is best treated by cauterization, or, if the lesion is very extensive, by an incision according to the method of Treves. Rectopexy, twisting of the rectum as recommended by Gersuny, and all attempts to constrict the rectum by means of silver wire are unreliable and dangerous procedures and ought not to be undertaken. For some weeks after operation defecation should take place while the patient is in the recumbent position.

Guaiacol in the Treatment of Malaria.—Whalen (*Chicago Med. Rec.*, July, 1899) has seen great improvement follow the use of guaiacol in those obstinate cases of intermittent fever in which quinin is without effect. The doses which he used varied from 5 to 45 minims. He began with 5 drops in capsules after meals, and gradually increased the dose unless disturbance of digestion followed. Some of the patients suffered from chills at irregular intervals while taking the guaiacol. Whalen attributed this to the fact that an insufficient amount of the drug was taken, and he continued increasing the dose until the stage of complete toleration was reached.

Massage of the Stomach and Large Intestine after Ingestion of Therapeutic Liquids.—Vogt (*Deut. Med. Zeit.*, No. 33, 1899) has ascertained that in the treatment of gastric troubles the effect of the remedies used is greatly increased if massage of the stomach follows ingestion. Light movements should be made from left to right over the whole gastric area in order to bring the liquid in contact with the mucous membrane of every portion of the stomach. To this end the patient should change his position several times during the séance. If the case is one of hypo-acidity, half a pint of normal saline solution or of a one-per-cent. solution of ichthyol should be given. If the latter is chosen it is to be siphoned out by means of a tube after the massage is finished. In cases of hyperacidity a 1 to 200 solution of Carlsbad salts may be employed, or a mixture of 3 drams of subnitrate of bismuth in 6 ounces of water. Bismuth, being very heavy, settles in the greater curvature of the stomach under ordinary circumstances, and therefore has very little effect; hence, massage is especially advantageous after this drug has been administered. If there is too great secretion, solutions of nitrate of silver, 1 to 1000 or 1 to 2000, may be employed. In lesions of the large intestine high injections of oil of the same temperature as that of the body are given and four hours later, the abdomen is massaged. If there is any suspicion of intestinal ulceration massage is contraindicated.

Treatment of Eclampsia.—Parisot (*Rev. internat. de med. et de Chir.*, March 25, 1899) states that the treatment of eclampsia aims to limit the production of toxins in the organism and to facilitate their elimination, when formed, through the skin, through the intestinal mucous membrane, and especially though the kidneys. Milk is the best food as it produces little fermentation, and favors diuresis. Insoluable antiseptics are given, salol, naphthol, benzonaphthol, etc., but according to Deschmaeker the best intestinal antiseptic is saccharin in divided doses, amounting to 1 or 2 grams (15 to 30 grains) a day. Purgatives are more to be relied upon than are intestinal antiseptics. Diuretic drinks, warm or vapor baths to increase the action of the skin, and inhalations of oxygen to increase the rapidity of combustion have their uses. Blood-letting is advisable if an attack is imminent. If there are nervous symptoms 15 to 30 grains of chloral and the yelk of an egg in 3 ounces of milk should be injected into the rectum. If this fails to quiet the patient, chloroform may be administered.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS in the form of Scientific Articles, Clinical Memoranda, Correspondence, or News Items of interest to the profession are invited from all parts of the world. Reprints to the number of 250 of original articles contributed exclusively to the MEDICAL NEWS will be furnished without charge if the request therefor accompanies the manuscript. When necessary to elucidate the text illustrations will be engraved from drawings or photographs furnished by the author. Manuscript should be typewritten.

SATURDAY, SEPTEMBER 2, 1899.

THE MARINE HOSPITAL SERVICE AND THE QUARANTINE OF OUR WESTERN COAST.

THE daily press at the beginning of the week contained the account of a conflict between the local and national quarantine authorities at the most important ports on our Western Coast. It was also announced that the Secretary of the Treasury considering the national authority paramount in the matter, had given instructions that the regulations made by the Marine Hospital Service should be enforced. It is hoped that this will definitely end the difficulty. With the present incidence of bubonic plague at so many seaports in the East, we cannot afford to permit any loopholes, however small, to exist in our Western quarantine without seriously risking an invasion of the scourge.

The present unpleasant incident at a moment of danger like this is a striking warning as to the evils of the present status of our system of quarantine. The Marine Hospital Service has given ample proof of its efficiency in enforcing quarantine regulations even under the most difficult circumstances. Until the establishment of a Department of Public Health with a member of the President's cabinet at its head, confident submission to the Marine Hospital authorities is the best guarantee that a city can have that its people will be properly protected. We are very glad to note that during the late unpleasantness at San Francisco, the city's Board of Trade and commercial organizations having the city's interest at heart recognized this fact. Let us hope that the conflict of quarantine authorities at such a time as this will promote the early establishment of a National Bureau of Health, as there is more and more necessity for uniformity of quarantine regulations of the kind that have proven thoroughly protective in practice.

THE SPREAD OF THE PLAGUE.

THE rumors of the spread of the bubonic plague beyond its first European port of invasion at Oporto have all happily been proven to be without foundation. Especially does it seem sure that no cases have occurred at Palermo, or Naples, or any other port of Southern Italy. Even the suspected cases at Lisbon have turned out to be other diseases falsely diagnosticated as plague during the first hours of excitement and alarm. All this, however, does not by any means give the assurance that Europe is out of danger. As the disease has once slipped in unawares, so may it again, and the present calm should lead to the relaxation of not a single precaution against it.

The plague has been particularly characterized during the present epidemic by just such fitfulness, with intervals of apparent cessation that disarm suspicion. We have heard time and again during this past five years that it was under control and no further spread of the disease need be feared, but it was always only to learn within a few months of its recurrence or invasion of adjacent territory.

We called attention some time ago to the fact that sanitary experts in India doubted if the plague could ever be eradicated from certain of the cities of the peninsula unless extreme measures were taken. The *Indian Medical Record* wrote editorially of the cities of Bombay and Calcutta as "doomed." We have reason to know from those who are in constant correspondence with pathologists in India that the latter consider the invasion of Europe by the plague as practically inevitable. All precautions in the past have not sufficed to prevent the spread of the disease in

India. New foci of infection have been lighted up, notwithstanding the high hopes and confident promises of sanitarians.

It may be noted in our Echoes and News column how insidious has been the progress of the disease. Plague has very probably been epidemic in a mild form in Alexandria since January. The disease has existed at Oporto since the beginning of July, although it was not until the middle of August that the official announcement of its presence was made. This circumstance possibly adds much gravity to the significance of the present situation.

The results of the latest pathological research in the disease are not calculated to allay uneasiness as to the possibility of its spread throughout the civilized world. It has been found that certain animals hitherto thought to be immune are liable to infection. The monkey, for instance, has been recently found dead from plague, and it is suspected that certain of the domestic animals are liable to it, especially in the virulent type of the disease has now developed as a consequence of its long continuance under conditions favorable to its growth.

There is every reason then to sustain the vigilance of quarantine authorities, and let the urgent danger be thoroughly and generally understood. We do not think that we exaggerate the significance of the present state of affairs when we speak thus plainly. An invasion of the Western World by the disease would be an incalculable evil. Every possible effort should be exerted to keep it off. While there is no reason for a senseless scare that would disturb commercial relations, there is every reason to commend the minutest precautions, lest commerce shall become the involuntary but effective carrier of the germs of an awful contagion.

THE PRESENT STATUS OF THE WIDAL REACTION.

The Widal reaction has come to stay. There can be no doubt of this now that the results of the army of earnest workers in this field have been given to the profession. In the early history of the reaction the medical press not infrequently contained reports of isolated cases in which the serum reaction was wanting, but in which clinical symptoms or even autopsy findings inclined the observer to the diagnosis of typhoid. Perhaps even more numerous were the evidences in favor of other diseases in cases in which the reaction was present. Influenza, malaria, pernicious anemia, acute miliary tuberculosis all contributed instances of undoubted reactions. No attention was paid to the fact that at least three of the above affections are not uncommonly mistaken clinically for typhoid fever, or that without absolute bacteriological findings or an autopsy (or in malaria the presence of the plasmodium of Laveran in the blood) they were not justified in their conclusions that they were not dealing with typhoid.

Then came the announcement that the blood of patients who had once been afflicted with typhoid may retain for years its agglutinative reaction. While this fact of itself was of some value, and necessitated a careful review of all those non-typhoid cases giving the reaction, of far more importance was it as an evidence of immunity to subsequent reinfection, *viz.:* the power attested by this reaction of the blood-serum of a patient afflicted with typhoid fever to destroy the typhoid bacilli entering its channels. In some patients this agglutinative power is exhausted before the patient has well entered upon his convalescence; a relapse occurs which may prove more virulent than the original attack. In others this power prevails over a period which can only be measured by years, three, five, or even longer.

To quote the statistics of Cabot: out of 5798 cases of typhoid, gathered from many sources both at home and abroad, the test performed in a variety of ways, with cultures obtained from many sources and of varied ages, positive reactions occurred in over 97 per cent., truly a remarkable result. But the scientific observer cannot rest satisfied with assurances of a positive character; negative evidence that the reaction does not occur in other diseases must be forthcoming. Cabot was enabled to gather from the same authorities almost as many instances of other diseases in which the application of the reaction gave negative results in fully 95 per cent. Of the remaining 5 per cent. we may rest assured that some of the subjects had had typhoid previously, and this fact of itself would help to better the record. By greater simplicity and unification of technic and by subjecting every case not typhoid but giving the reaction to careful investigation to determine if the disease has formerly existed we may confidently expect an even greater percentage of positive reactions in typhoid

and of negative reactions in our control experiments.

There is one point in which our statistics are somewhat lacking, and that is the percentage of typhoid (the existence of the disease being absolutely proven by post-mortem findings) that exhibits a positive reaction, provided the serum is taken from the body some time before the onset of the death agony. In the experience of the writer, and other observers have narrated the same, the serum when taken just before death does not always give a positive reaction though previous tests may have proved its presence unmistakably and the autopsy showed the characteristic lesions of typhoid.

Following closely on the heels of Cabot come the statistics of Anders and McFarland, published in the *Philadelphia Medical Journal* of April 8, and 15, 1899. These observers, in testing the blood of 230 typhoid patients, relics of the Spanish-American War, found the reaction in 219, or in more than 95.5 per cent. Stengel and Kneass in the "Year-Book of Medicine" (1898) collected reports of more than 2000 cases of typhoid in which the reaction was found in 95.5 per cent., while in almost 1500 non-typhoid cases the reaction was present in only about 1½ per cent. We have, then, a test for typhoid, which, when performed with proper precautions, if not absolutely diagnostic, is certainly one of the most reliable signs of the disease. It is not frequently present in other diseases, if at all, as is the diazo reaction of Ehrlich, nor is it so difficult though far more reliable than the leucocyte count. It has certain limitations, it is true. As a rule, while not appearing during the first few days of the disease, it is manifest before the rose-colored abdominal eruption appears. Occasionally it does not appear before the fourth or fifth week, from which it may be inferred that patients dying of the dangerous complications of the second or third week may never have given a positive reaction. A previous attack of typhoid within a period of one to three years interferes absolutely with the value of the reaction. It is frequently not present if the blood is withdrawn while the patient is at the point of death.

ECHOES AND NEWS.

Death Due to Hiccough. — A patient died of hiccough in the General Hospital at Matteawan, N. Y. The attack began on August 20th, and despite treatment he was not relieved and died of exhaustion on August 25th.

Hurricane Death-List.—It is estimated that the bodies of 2500 victims of the recent hurricane at Ponce, in Puerto Rico, have been buried, that 1000 other persons were injured during the storm, and that 2000 people are still missing.

Death at 116 Years.—William Gaffney, who died at St. Bazile in Canada on August 24th, was 116 years old. He was born in Ireland and came to Canada eighty-five years ago. He was able to walk about, and had all his faculties up to a few hours before his death.

Typhoid Fever in Boston.—There is in Boston an increase of about thirty-six per cent. in cases of typhoid fever during August over the corresponding time in 1898. It is believed that most of the recent cases which have developed have come from some sort of infection through the milk-supply.

Smallpox in Texas.—An epidemic of smallpox has broken out in Texas as a result, it is believed, of the bad sanitary condition following the recent disastrous floods in the Brazos Valley. Hundreds of negroes in Bastrop, Brazos, Robertson, and other counties are afflicted with the disease. The State Health Department has taken charge of the situation.

The Malarial Mosquito Found (?).—Major Ross, who was sent to Sierra Leone by the Liverpool School of Tropical Diseases to try to discover the malarial mosquito, has telegraphed to Professor Jones, of the school, that the mosquito has been found. It is believed that the English Government will send medical experts to assist in the researches.

Hospital Corps Men Needed.—Much difficulty is being experienced by the War Department in procuring men for the hospital corps and signal service. The increase of the Philippine army to 63,000 men will necessitate a corresponding increase in these services. Fully 2500 hospital corps men will be needed, the calculation being based on an estimate of six per cent. of the combatants being incapacitated for active duty.

Temperature at Manila.—Lieutenant W. C. Davis, now at Manila, wrote on June 29th to a friend in Baltimore to the effect that through May and June, the hottest months in the year in the Philippines, the climate was quite comfortable. On the hottest day it was 88° in the shade. At night it becomes cool and blankets are necessary. "It is," he stated, "nothing like as hot at Manila as it is in the summer in the Eastern part of the United States."

Unpopular Medical Men.—In New Zealand the medical profession is disliked among the working classes. They never apply to a doctor until all other means have failed, refusing when they do call upon him to give their symptoms, and expecting the physician to make a diagnosis by merely looking at them. Should he be indiscreet

enough to say, "Well, what's the matter?" the patient would grin most disrespectfully and tell the doctor it is his business to find out.

Professor Grassi's Malarial Studies and the Italian Health Authorities.—It is considered that so much excellent work on malaria has been done already by Professor Grassi, Lecturer on Comparative Anatomy at the University of Rome, and there is promise of so much benefit to public health in the continuance of his studies, that the Italian Superior Council of Health has granted a fund to defray the expenses of his further investigations into the etiology of malaria and methods of preventing the spread of the disease.

Fighting Pests with Biologic Aids.—There is a plague of locusts afflicting India in addition to that unfortunate country's other ills, and the inhabitants are trying a new method in fighting it. It has been found that a certain fungus is very effective in disposing of the insect pests. This fungus is now being distributed to the farmers of locust-infested districts, by the British Army Medical Service in India. It is hoped that its presence will succeed in inhibiting the almost annual invasion by the destructive insects.

Prizes for Life-Saving Devices at Sea.—A series of prizes for this very commendable object are to be given by members of the Pollok family. Certain members of the family were lost last year by the sinking of the Bourgogne and the present offer is dictated by that circumstance. The prizes are to be awarded at the Paris Exposition next year and the competitors of every nationality are expected to take part. Mr. William Ker of Washington, D. C., has been selected as secretary of the committe in charge of the competition in America.

Artificial Culture-Medium for Lepra Bacilli.—Dr. Carrasquilla of Bogota, United States of Columbia, well known for the invention of a lepra serum, with which he has been experimenting, announces that he has been able to cultivate lepra bacilli outside the human body on artificial media. This has not been successfully done up to this. The media Dr. Carrasquilla has had his success with were sloped human blood-serum and beef bouillon prepared according to the formula in general use in bacteriological laboratories in France. The formula may be found in French text-books of bacteriology, especially Thoinot's.

Quinin in the United States Army.—More than 125 million grains of quinin have been taken by United States soldiers during the past year. It is said that some of the military patients in the army hospitals in Cuba and Puerto Rico took as much as 300 grains a week during several weeks. Hardly any of those who were in service in the West India islands failed to take some quinin during their stay. A military correspondent writing from Puerto Rico recently said that practically none of the soldiers had been entirely exempt from malarial disturbances on that island and that while the malaria was usually not severe it was very obstinate.

Smallpox in New York State.—The State Board of Health is sending circular letters to the Health Boards of the different cities, calling attention to the prevalence of a mild form of smallpox in the central and western parts of the State. It is stated that the spread of the disease at this time, as was the case a year ago, may be attributed in a large degree to the fact that many cases of smallpox were mistakenly diagnosticated chicken-pox, and it is advised that the various city boards adopt and enforce rules requiring that all cases of supposed chicken-pox be reported promptly to them, in order that they may be kept under observation, and quarantined, if necessary, until all doubt is at rest.

The Continental Anglo-American Medical Society.—This association, which is composed of English-speaking medical men (British and American) who practise on the Continent, held a meeting at Portsmouth during the recent meeting of the British Medical Association. Professor William Osler of Johns Hopkins, who is one of the vice-presidents of the Society, occupied the chair. A number of the most prominent members of the medical profession in England were present. Speakers insisted on the evident advantage to be derived from English practitioners being acquainted with the physicians to whom they might have occasion to send patients visiting the Continent. Professor William Osler dilated on the advantage of being an Anglo-American-Canadian when events were tending to bring all branches of the English-speaking world in closer touch with one another.

Insanity among Indians.—An expression of opinion in this matter from one who ought to know of what he speaks, and that is of a great significance to medical men, we take from a recent number of the *Scientific American:* "United States Commissioner William A. Jones makes the interesting statement that 'a full-blooded Indian lunatic never lived.' After inspecting the site recently purchased by the Government for an Indian Insane Asylum in the Indian Territory, he says, 'The occupants of the hospital which will soon be opened will all be mixed breeds. Probably there never was a case of insanity in any tribe until the malady was introduced by mixing with the whites.'" It would be interesting to know what reasons experts in mental diseases give for this exemption of the Indian from mental trouble. Now that it seems definitely sure that insanity is largely on the increase in civilized communities the theories of explanation would be especially of interest.

The Utilization of Putrid Meat.—In France nothing is allowed to go to waste. Meat unfit for food and the bodies of animals that have died of disease are extensively used for the manufacture of superphosphates. The meat is placed in a vat containing sulphuric acid, which separates the resulting nitrogenous product from the fat. The dead animals are thrown whole into covered lead-lined vats full of sulphuric acid of 66° Beaumé. If these animals have died of anthrax or glanders they are cut up before being thrown in. In the course of forty-eight hours the fat alone remains, and the animalized

sulphuric acid, rich in nitrogenous substances, is drawn off and sent through an underground conduit to the superphosphate factory. Thus, instead of the unsanitary method of burying such putrid substances directly in the ground, they are effectually disposed of by the complete destruction of all injurious germs; and there results a product available in the manufacture of a valuable fertilizer.

Mine Accidents and Fire-Damp.—Professor Haldane, Lecturer on Physiology at Cambridge University, England, has had the opportunity recently to investigate the causes of death among the miners in an explosion in an English mine. Out of fifty-eight victims only two were injured enough to cause death; the remaining fifty-six were asphyxiated by the products of combustion present in the air after the explosion, and by the absence of oxygen. The effective cause of death in the fatal cases was principally the presence of large quantities of carbon dioxid in the air. It is the presence of this gas, too, that makes the work of the rescuers so difficult and dangerous. The gas is absolutely odorless and does not betray its presence until men are overcome by it, when often it is extremely difficult for the others of the party to carry them out of danger. Professor Haldane has found that mice are extremely susceptible to carbon dioxid and succumb when such proportions of the gas are present in the air as men endure very well. He suggests, then, that rescuing parties should carry mice with them (they are, as a rule, not difficult to procure around mines) to furnish an index of the presence of carbon dioxid in the atmosphere just short of the danger-limit. They would serve as a warning and changes in the direction of the air-current of the mine might be made after this indication, which would eliminate some of the danger.

The Nobel Prizes.—It is well known that the Swedish inventor of dynamite, the late Alfred Nobel, left a very large sum of money to be distributed in prizes for scientific and other advances. His executors now announce that the estate amounts to $7,500,000, which has been invested, and $40,000 will be available for each of five annual prizes to be given for discoveries and inventions in physics, chemistry and medicine, and for the most deserving work in literature respectively. The fifth prize is to be awarded to the person who has done the best work for the fraternization of nations, for diminishing armies and the propagation of peace during the year. It is well known that Nobel himself, though the inventor of dynamite and a great manufacturer of high-power and smokeless explosives was an ardent advocate of universal peace and the establishment of international arbitration. He even persuaded himself that he had in his invention of the more powerful explosives advanced the coming of the millennium of international fraternity by making war more terrible and more absurd. The first distribution of these prizes will take place with the beginning of the new century in December, 1901, as directed by the donor's will. The distribution day annually is to be December 10th, the anniversary of Alfred Nobel's death. The prizes are to be decided by certain institutes founded for the purpose in Sweden. Recommendation of contestants for the prizes is to be made by various scientific and literary societies and academies and universities designated by these institutes. Competition is, of course, open to the world and besides the $40,000, each prize-winner will receive a diploma and a gold medal bearing a relief representation of the prize founder. Personal application will be entirely useless and application can only come through one of the designated scientific or literary institutions. As further details are made known they will be noted in these colums.

Obituaries.—Dr. John J. Linson died on Sunday, August 27, at Tarrytown, N. Y. He was born in New York City in 1827, and was a graduate of the College of Physicians and Surgeons of New York. After having served at the front with distinction during the early part of the Civil War as the surgeon of the Sixth New York Heavy Artillery, he became surgeon of the Provost Marshal's office in the New York district, and invented the method of marking volunteers with nitrate of silver, which proved so effective in preventing the wholesale bounty jumping so common at one period of the war. He was president of the Westchester Medical Society for three years.—Dr. Max Thorner, a brilliant pupil of Dr. Virchow, died at Cincinnati, Ohio, on August 27th. He was only thirty-nine years old. He was a laryngologist of note, and held the chair in that branch of medicine at the Cincinnati College of Medicine and Surgery. At the last meeting of the American Laryngological Association he was unanimously elected a Fellow, a rare honor, as the association's membership is limited to seventy-five. He was also a Fellow of the American Rhinological and Otological Society.—Dr. Josef Mayer, sometime Surgeon-General of the Polish Army, and Professor, Dean, and Rector of the Jagellonian University, Cracow, died recently, aged ninety-one. He was a member of the Polish Academy of Medicine, of which he was president for many years, and he was a member of a number of other societies, Polish and foreign, a member of the Austrian House of Lords, and for a long time a Deputy for his district, and a Town Councillor for Cracow. In his person was embodied nearly a century of the intellectual life of Poland. Born at Cracow in 1808, he studied in the University of that city, and took his doctor's degree in 1831. He took part in the Polish rising of that year, serving in the army of his country as a medical officer. He was the author of nearly eighty books and papers on the physiology of the nervous system, physiology of the senses, the length of man's life, the influence of meteorological conditions on mortality, etc. He had been a professor at the University of Cracow for more than sixty-six years, having been appointed to his chair while Cracow was an independent duchy, and retaining it after the city and university passed under control of the Austrian Government.

The Plague Situation —Two items of very great interest as regards the present plague situation we copy from the *British Medical Journal* for August 19, 1899. They serve to show very forcibly the insidious character of the

disease: "The appearance of the plague in Portugal is ascribed to packages from Bombay landed in Oporto early in July, 1899. The latest advices mention 36 cases of plague and 6 deaths; but Reuter's Lisbon correspondent states that on August 11th 'several cases of plague have been reported in the central quarter of Oporto. It is said that since the first outbreak of the epidemic there have been 27 cases and 11 deaths.' All ports in the Azores are closed to Portuguese vessels, and the Brazilian Government has imposed quarantine on vessels which left Portuguese waters after July 1st. The Spanish authorities are in the greatest perturbation, however, and they have good reason to be alarmed. Many Spanish families are at watering-places in Portugal, and the authorities are afraid that their return may carry plague to Spain. The sanitary authorities in Spain have decided to impose quarantine on arrivals from all Portuguese ports, to establish five lazarettos on the frontier, and to interrupt all communications both for goods and passengers between Spain and Portugal until the lazarettos are prepared. There may be some consolation in the fact that the cases are not numerous nor is the disease spreading. This is confirmed by the fact that the death-rate of Oporto is not abnormal. As usual, notwithstanding the official announcement, many residents in Oporto and throughout Portugal are sceptical as to the real existence of plague, and are prepared to deny its presence. This is the usual condition of things, as in every country and town where plague has appeared we find persons ready to suppress the truth, and deny the possibility of its presence." From Alexandria recent news is of similar and epidemilogical interest: "A telegram from Alexandria, dated August 13th, reports that after a week's interval 1 fatal case of plague was reported on August 10th, and that 3 new cases and 2 deaths from plague have occurred during the week ending August 13th. A report dated July 25, 1899, has been addressed to the Constantinople Sanitary Administration by the Ottoman sanitary delegate (Dr. Duca) in Egypt on the supposed origin of the present outbreak of plague in Alexandria. Dr. Duca states that Dr. Doxara, in January, 1899, saw a case of buboes with fever in Alexandria. During the ensuing months several such cases occurred, but he did not draw the attention of the government to the fact. When the plague, however, was officially declared in May, 1899, Dr. Doxara reported the cases of bubo with fever he had observed during the previous months. The cases were sporadic, of a mild type, and chronic in their nature. Dr. Doxara states that owing to the slowness of the spread it might appear that the mild type of cases he mentions were not plague nor in any way connected with it, but he draws attention to the fact that in all the epidemics of plague occurring between 1835 and 1843 in Alexandria, similar mild cases of plague always preceded the outbreaks of true plague. Dr. Doxara remarks that there has been direct communication between Bombay by steamers of the Italian 'Rubattino' line ever since November, 1898. Many passengers were landed from these boats—including the passengers of the s.s. 'Mehalla,' on board which a stoker developed plague—and went to various parts of the country. In addition, thousands of sacks of grain from Bombay were landed on the wharves at Alexandria during the early part of this year. Dr. Doxara is of the opinion that the present outbreak of plague has not occurred suddenly, but that the disease has been present in a mild form (pestis minor) for several months before it was diagnosed or officially declared to exist in Egypt. As a guide to the period of the year at which plague is apt to prevail most seriously in Alexandria, the following extracts from observations extending over ten years, 1834-1843, is interesting: January, 329; February 1112; March, 4952; April, 2936; May, 1799; June, 547; July, 216; August, 100; September, 15; October, 18; November, 63; December, 195. It would appear that when the plague prevails at Alexandria it is wont to reach its maximum of virulence during the spring and to subside almost to vanishing point in the autumn." At Mauritius the plague continues to rage with unabated virulence. The British Colonial Office has received information that during the week ending August 19th, 40 new cases of plague and 32 deaths occurred. At Hong Kong the number of new cases of plague which occurred during the week, August 14th to 20th, was 20. During the same period there were 20 deaths from the disease. A telegram to Shanghai from the British Consul at the treaty port of New Chang, in North China, reports that the bubonic plague has appeared there. It is feared that the bubonic plague is epidemic on the Gold Coast of Africa, carried there from the neighboring French colonies, where it is known to exist. A French priest is reported to have said that 13 of the fathers and sisters, a d upward of 40 European merchants and officials, had succumbed within the last three months. The latest reports from Europe show that plague exists only in Portugal, and is not spreading there to any extent. A case is said to have occurred in these last few days in the prison at Oporto, and this may prove of serious import.

MEDICAL MATTERS IN NEW YORK.

NEW YORK'S ACCOMPLISHED POLICEMAN—AN EPIDEMIC OF DEATH—THIEF DIES IN JAIL—SCIENTISTS TO MEET IN NEW YORK — DEATH OF DR. M'LEOD — CLINICAL INSTRUCTION FOR FEMALE MEDICAL STUDENTS—OFFICIAL HOSPITAL INSPECTIONS—REGULATED CHARITY.

GEORGE H. QUACKENBOS, a patrolman on the New York police force, reads Greek, understands the sign language, is a good telegraph operator, has filled the chair of rhetoric in Seton Hall, New Jersey, and lastly holds the degree of Doctor of Medicine of the New York University Medical College. He is the son of Professor George W. Quackenbos, Professor of Greek and Latin at De La Salle Institute. When Governor Roosevelt was president of the Police Board he appealed to educated men to become policemen. Quackenbos, reading of this in the papers, made application and joined the force. Some time ago a contributor to one of our medical journals presented a paper in which he demonstrated that but

seventeen per cent. of medical graduates continue in the profession of medicine. All the rest go after graduation into other pursuits. Quackenbos is probably the only man who has forsaken medicine to wear the uniform of "the finest."

Mrs. Bathje, a resident of Brooklyn, seventy-two years old, died on August 26th from a fractured skull due to a fall from the window of her daughter's apartments. The daughter, Mrs. Reynolds, has lost by death within the last six months her mother, father, husband, and three children.

Some time ago the New York Health Board received a number of complaints of thefts committed by a man who represented himself to be "Dr. Wood, a Health-Board inspector." The man gained access to many houses, and the police estimate the aggregate amount of his thefts at about $20,000. He recently left New York, and transferred his operations to Newark, N. J. Here he was arrested on August 17th, and extradition papers were prepared for bringing him here for trial. However, he died in jail of Bright's disease on August 22d.

The next meeting of the American Association for the Advance of Science will be held at New York, June 25–30, 1900. Its officers are: President and treasurer, Robert Simpson Woodward, Dean of the School of Applied Science of Columbia University, and Professor of Mechanics in the same university; permanent secretary, L. O. Howard of Washington, Government Entomologist; general secretary, Charles Baskenville of Chapel Hill, N. C.; secretary of the council, William Hallock of New York.

Dr. Samuel B. McLeod died on August 22d at his home at 339 West Twenty-third street. He was injured several weeks ago in alighting from a Madison avenue trolley-car, but it was thought that he had recovered from the accident. It aggravated an old heart lesion, however, to which the doctor succumbed. He was a cousin of the late Dr. C. R. Agnew. His father was the Rev. J. N. McLeod, for forty-four years pastor of the Reformed Presbyterian Church on West Twelfth street. Dr. McLeod graduated from the New York College of Physicians and Surgeons, was for two years vice-president, and afterward for five years president of the New York County Medical Association. He was also vice-president and president of the New York Medico-Legal Society, a permanent member of the American Medical Association, consulting physician to the Marion Street Maternity Hospital, and consulting physician to the Northern Dispensary.

The medical instruction to be given in future at the New York Infirmary for Women and Children will consist of special courses for women graduates and undergraduates, under the charge of former professors and instructors of the Medical College of the Infirmary which was closed last June. The fine opportunities for study afforded by the hospital wards and by the dispensary and out-practice services, heretofore absorbed by the students of the college, are now open to all women students of medicine.

Comptroller Coler and President John W. Keller of the Department of Charities visited Bellevue Hospital and the institutions on Randall's and Blackwell's Islands on August 22d. Both these gentlemen are anxious to put a stop to the granting of city money to private institutions, and when the budget of 1900 is made up it is intended to make a strong fight to have the grants of public money reduced. It is proposed to stop the sending of rich persons to private hospitals at public expense when there is room for them in the institutions controlled by the Department of Charities. This department has fully equipped modern wards and pavilions for the treatment of every class of disease. These wards are at times practically empty but the expense of maintenance goes on whether there is one patient or twenty in them, being reduced only by the cost of food for patients. At the same time the municipality is paying large sums for the treatment of patients in private hospitals. Mr. Coler and Mr. Keller believe that the reform in the dispensation of charity by the city should begin with this abuse and it will be one of the things for which they will contend in the Board of Estimate.

In the communication sent by the New York State Board of Charities to Comptroller Coler in answer to his request for advice—which was noticed in this column last week—it was further observed that when a group of persons organize a charitable institution, the natural and usually sufficient check upon its undue development is the necessity resting upon them of giving or securing from others the necessary funds for its maintenance. This necessity is the natural check upon the tendency of all institutions to grow indefinitely, to admit children who ought not to be received and to retain children who would be better off if placed in families or returned to their parents. The securing of public funds removes this natural and wholesome safeguard against undue growth. At present several of the large institutions whose payments have met not only all the current expenses of every nature but have left an excess to be applied to the reduction of indebtedness, or the erection of larger buildings are wholly supported by the city. In summing up it was stated that in the opinion of the committee who formulated the answer to the Comptroller the plan of granting public subsidies to private institutions has inherent and grave dangers which it is impossible to obviate, and that no plan can be devised which will insure wholly satisfactory results. Appropriations of public money to private institutions inevitably tend to diminish and discourage private charity. The present system confuses the duties of the public authorities and of private citizens and private organizations, and prevents any clear division of the field as between public and private effort. It encourages the growth of privately managed but publicly supported charities to an unlimited and harmful extent. Though often apparently economical in the beginning it is always in the long run enormously expensive. It indirectly prevents a proper equipment and maintenance of the public charitable institutions. And lastly, its permanent disadvantages far out weigh any immediate temporary benefit that may be derived when the system is first established.

MALIGNANT NON-SEPTIC RHEUMATIC ENDOCARDITIS—FREEZING-POINT OF THE BLOOD AS A MEASURE OF THE COMPETENCY OF THE KIDNEYS—SIGNIFICANCE OF THE STRUCTURE OF THE RENAL ARTERIAL SYSTEM.

AT the Berlin Medical Society on June 21, 1899, Litten read a paper on the malignant non-septic form of rheumatic endocarditis. The septic form of endocarditis may be produced by pneumococci, gonococci, typhoid bacilli, tubercle bacilli, diphtheria and influenza bacilli, colon bacilli, streptococci, staphylococci, etc. The ordinary rheumatic endocarditis is usually spoken of as the verrucose form. In the latter there is a tendency for fibrin masses to form upon a valve. These masses undergo a benign metamorphosis. They do not entirely disappear, but shrivel up so that they are relatively harmless. This form of endocarditis as all others is produced by micro-organisms which are seldom found because the opportunity to make a post-mortem examination in a recent case rarely comes to pass. Simple rheumatic endocarditis affects usually the left side of the heart in contradistinction to the fetal and malignant forms. The explanation of this fact is found in the necessity for oxygen which the germs exhibit. As the left side of the heart is supplied with freshly oxygenated blood germs can live and develop in this side of the heart far better than in the right side. In the fetus on account of the absence of air in the lungs and the presence of the foramen ovale the blood in the two sides of the heart contains practically the same amount of oxygen. As the right side of the heart does more work in the fetus, it may be supposed that it is more liable to injury, and hence offers a more favorable seat for the development of the micro-organisms. Simple rheumatic endocarditis is not a complication of acute rheumatism but is a localization of the morbid process. This form of endocarditis never gives rise to abscesses or malignant metastases. If infarcts are caused they are not infectious. It exhibits a great tendency to recurrence. It is often complicated by fibrinous endocarditis. It has no characteristic type of fever as have the malignant forms, for the reason that it runs no specific course, and new lesions are frequently superimposed upon old. In the swollen and painful joints is found a clear or slightly turbid but never purulent fluid. Another diagnostic point is the prompt effect of the salicylates upon the general condition and the swelling about the joints. Endocarditis occurs, according to different observers, in from sixty to seventy-five per cent. of the cases of acute rheumatism, but apparently every heart which gives a systolic murmur is counted by them as rheumatic.

The term "ulcerative" endocarditis is less suitable than the term "septic." Oftentimes the patient dies before the papillary growths upon the endocardium have advanced sufficiently to undergo necrosis. This form of disease is due, as already stated, to the action of various cocci, bacilli, etc. It occurs in the right side of the heart as well as in the left. The infarcts produced are rarely benign, and they usually lead to metastatic abscesses. Microbes which cause septic endocarditis usually come from broken-down thrombi in the veins; hence the endocarditis is merely a symptom of the pre-existing disease. If pericarditis co-exists, it is almost always suppurative, not fibrinous. This form of endocarditis is often complicated with hemorrhagic nephritis. Etiologically, its occurrence is most often due to diphtheritic inflammation of the site of the placenta after abortion or normal birth; to diphtheritic inflammation of the intestine, of the soft palate, of the vulva, or of the uterus: to severe affections of the adnexa with thrombo-phlebitis; to phlegmonous parametritis; to suppurative inflammations of the neck after scarlet fever, or typhoid fever. Clinically speaking, septic endocarditis runs an acute course, usually terminating in death. The temperature is high; there are irregular chills, either daily or every second day, or at no stated intervals. Hemorrhages in the skin or retina occur in eighty per cent. of the cases. Various kinds of suppurative processes appear in the skin and eye, such as severe pemphigus, multiple abscesses, deep necrosis of the skin with hemorrhages, panophthalmitis. The spleen is invariably much enlarged, although sometimes it cannot be felt during life. It may contain abscesses and be surrounded by fibrinous inflammation so that a distinct râle may be heard and felt on respiration. This form of endocarditis causes changes in the pulse, in the activity of the heart, and in the respiration of such striking character that they are easily differentiated from the symptoms of the rheumatic form in which the variations take place slowly. The disease leads rapidly to death. In the blood immediately after a chill are found the same micro-organisms as are found in the fluid aspirated during life from the joints, and post-mortem in the cardiac lesions. The important point in etiology is the presence of necrotic thrombi in the veins.

The third form of endocarditis, to which LITTEN has given the name of malignant rheumatic endocarditis, usually terminates in death but is not septic. The severe character of the infection appears early in the disease, and to a certain extent simulates in this respect that of the septic form. The objective signs in the heart are like those of the simple rheumatic form, only more extensive. There may be a feeling of oppression and dyspnea. The patient soon becomes anemic, cyanotic, or unconscious. The fever may be slight or it may be very high, of an irregular character, and interrupted by chills. There is swelling of the spleen. There is a positive diazo-reaction of the urine. Often cutaneous, mucous, and retinal hemorrhages occur. Hemorrhagic nephritis is a common symptom. The metastases which are formed are invariably benign, giving rise to simple infarcts and anemic necrosis. The disease lasts for many weeks, and terminates in death after severe cerebral symptoms.

The writer stated that he had treated twenty patients, nineteen of whom had died, and the remaining one was still very ill and likely to die. This form of endocarditis develops in the course of an acute rheumatism or an

acute rheumatism or an acute rheumatism complicated with chorea. One diagnostic point is the prompt effect of the administration of salicylates upon the general affection. If the cardiac lesions, instead of remaining stationary or diminishing, show a tendency to increase and grow worse, the case will probably be found to be one of malignant and not one of benign endocarditis. Fluid aspirated from an affected joint is never purulent. After the administration of salicylates and improvement of the condition of the joints, the patient may have a sudden chill or cutaneous hemorrhages may occur causing the physician to examine the heart. In this form of endocarditis the right side of the heart may be affected as well as the left. The fever presents no regular type. There are no abscesses in the skin or in the eye. Retinal and cutaneous hemorrhages are unfavorable symptoms. There may be an enormous increase in the pulse-rate, possibly to 160 per minute; cardiac irregularity, palpitation, and marked dyspnea. Other patients do not have these extreme symptoms, or only after exertion. The swelling of the spleen can usually not be made out during life. After several weeks the patient becomes very anemic and exhausted; symptoms of oppression and dyspnea and cyanosis set in or cerebral symptoms develop and death follows. At post-mortem examination no suppurative processes nor thrombophlebitis will be found. Such metastases as exist will be of a benign character. Fibrinous pericarditis is frequently an accompaniment. There are usually numerous hemorrhages into the serous membranes. In two cases Litten's assistant was able to demonstrate the presence of very small cocci in the blood. The writer emphasized the importance of recognizing this malignant form of endocarditis at an early stage.

At the session of June 21st, RICHTER and ROTH presented the results of their experiments in reference to nephritic incompetency. The desirability of recognizing whether the kidneys are satisfactorily performing their duties needs no argument. It was formerly supposed that if they were working properly a certain amount of urea, chlorids, etc., would be excreted daily; that, therefore, an examination of the urine would show whether renal incompetency was present or not. This is not always the case for the reason that it is not the absolute work of the kidneys which is important but the relative work—that is, the amount of work performed relative to the amount demanded. No matter how much work done there is renal incompetency if the kidneys are not able to prevent the retention in the body of products of metamorphosis. Hence the desirability of being able to determine this by examination of the blood. Such an examination to be of practical importance must be simple and easily carried out. Koranyi has recommended such a method. It consists in testing the molecular concentration of the blood-serum by ascertaining its freezing-point. Blood-serum possesses normally a constant molecular concentration. During the process of metamorphosis in the body large complex molecules of albumen are broken up into numerous small molecules. Molecular concentration of the blood is thereby increased. The kidneys constantly counteract this tendency by excreting from the blood a concentrated fluid, thereby preventing the accumulation in the blood of an excess of the products of metamorphosis; hence, the constant normal freezing-point of the blood is a sign of the sufficient action of the kidneys. If the kidneys fail in their activity, there is an abnormal molecular concentration of the blood which is plainly shown by an abnormal sinking of the freezing-point. The freezing-point of normal blood is not more than 0.56° less than distilled water. If it is lower than this it is an indication that there is renal incompetency. More recently it has been found that insufficient oxygenation of the blood will also reduce its freezing-point. But this error can be eliminated by shaking the blood with oxygen in a test-tube. If the low freezing-point is due to lack of oxygen, it will rise; if it is due to renal insufficiency, it will not be affected by the oxygen.

At the session of June 28th, ZONDEK showed macerated preparations of the arterial system of fifteen kidneys and called attention to certain facts in connection with the vascular supply of the kidney which have an importance in connection with the surgery of this organ. The frequent existence of a second artery to one pole, may explain why tuberculosis is so often limited in its distribution in this organ. This arrangement of arteries is also to be borne in mind in nephrectomy, as its neglect has given rise to serious hemorrhage. The arterial supply of the capsule is distributed over the anterior and posterior sides of the kidney and to its two poles. Paranephritic abscesses are generally found in one of these four positions. The freedom from anastomosis of all the little arteries in the substance of the kidney explains the occurrence of multiple abscesses. In resecting portions of the substance of the kidney the operator should excise a pyramidal or cone-shaped piece, in order to avoid wounding the arteries which radiate from the hilus. In nephrotomy the incision should not be made down the back of the kidney as in an autopsy, but in the middle third of the lateral surface, parallel to the median line of the dorsum, and about one-third of an inch removed from it. The incision should be oblique with reference to the renal surface, the knife being slanted downward toward the hilum, so as to open into the pelvis as directly as possible. This incision gives the best chance to find a calculus when the pelvis is small, and avoids all large arterial branches, and thus diminishes the risk of hemorrhage and of subsequent colic, and economizes the renal tissue to the greatest possible extent.

SOCIETY PROCEEDINGS.

THE BRITISH MEDICAL ASSOCIATION.

Sixty-seventh Annual Meeting, Held at Portsmouth, England, August 1, 2, 3, and 4, 1899.

[Concluded.]

SECTION ON STATE MEDICINE.

DR. J. GROVES in opening the discussion on

PERSONAL COMMUNICATION OF TUBERCULOSIS AND THE MEASURES AVAILABLE FOR ITS PREVENTION,

said that twenty-five years ago phthisis was supposed to

be a purely hereditary disease: now it is known to be communicable, and as such must necessarily come under the cognizance of the sanitary officers. But authorities are not yet agreed as to the degree of this communicability. He was not at present in favor of notification, which would result in the breaking up of families. Phthisis is on the decrease in consequence of better ventilation and sanitation.

DR. A. NEWSHOLME said that all present views of phthisis are founded on the idea of its communicability. Notification should be enforced on quite different lines from those applied to the more acutely infectious diseases. It is a communicable disease, but its communicability is much more manageable than that of other infectious diseases, seeing that it has to do almost solely with disinfection of the sputa. The medical officer of health should be associated with the family doctor in notification. The advantages derived from inspection would give the greatest success in the prevention of phthisis. There is in Brighton a modified system of notification. Dr. Newsholme gave particulars of the visits recently made in fifty-six such cases. He advocated the giving of a fee for voluntary notification, which he wished to be adopted. Visits of the medical officer of health should be confined to those cases in which the medical man attending makes no objection. In certain districts compulsory notification might be even now adopted, without penalty in the event of the practitioner objecting to notify.

DR. NEWSHOLME spoke on the

MEANS OF PREVENTING THE SPREAD OF INFECTION IN ELEMENTARY SCHOOLS.

Other measures are even more imperative than the medical inspection of schools and scholars. These are the provision of prompt medical attendance upon children who become ill, in order to secure an early diagnosis, with proper treatment and isolation if necessary. Medical inspection of scholars, with the bacteriological investigation of their discharges (nasal, aural, etc.), has only a limited utility in preventing the spread of infection. To combat such diseases must be chiefly the affair of parents and private medical practitioners. Absentee scholars who are ill should be visited at home for diagnostic purposes alone by the medical officer of the school; but the public is not yet prepared for such an innovation. The speaker described and exhibited the forms used in Brighton for the notification of infectious diseases by school authorities, and stated the advantage accruing from their use, especially in the obtaining of an increased school grant.

DR. H. R. KENWOOD considered that all pupils in schools should be examined twice a year at least in non-infectious times; whereas, the inspection might be made daily in times of epidemics. Prizes for maximum attendance should be abolished, as children, in order to obtain them, often attend when for medical reasons they should be at home, if not in bed.

DR. A. NEWSHOLME concluded by moving a resolution requesting the Council of the British Medical Association to make representations to the Education Department, urging upon the department the necessity, from the standpoint of the public health, of authorizing medical officers of health to inspect all school premises, and to inspect or secure the inspection of scholars when the prevalence of infectious disease is judged by him to make such an inspection desirable. The resolution was carried unanimously.

DR. J. K. BARTON read a paper in which he insisted that the prevalance of decayed teeth in children is due to artificial feeding with improper food. The use of sterilized pure cow's milk would prevent such decay of teeth, which is especially prevalent among rickety children. The examination of the teeth of children in schools is done too late to prevent the decay, which is due to improper feeding in infancy.

SECTION ON DISEASES OF CHILDREN.

The second meeting of this section was opened by DRS. A. M. GOSSAGE and J. A. COUTTS on

THE ETIOLOGY OF CONVULSIONS IN INFANCY.

They pointed out that true convulsions are much more infrequent than is generally supposed. Predisposing causes are more important than exciting causes. The instability of the infantile nervous system is one cause, but there are others, such as inherited neurotic conditions and rickets. The alleged frequency of teething and digestive disturbances, convulsions as merely the equivalent of signs at the onset of acute diseases and exanthemata, and the convulsions in asphyxia were discussed.

DR. HUGH JONES regarded all convulsions as symptomatic only. Of recent years there has been a fall in the number of recorded deaths from convulsions, corresponding with a decrease in other diseases, and with improved general sanitation. Dr. Jones attributed the majority of the cases to bad feeding. A symptom is not the cause of death, and certificates of death should be accurate and precise. Death cannot be combated by registering symptoms.

MR. JOHN LANGTON, who read a paper on

THE TREATMENT OF INGUINAL HERNIA IN INFANCY AND CHILDHOOD,

gave statistics regarding the relative frequency of the condition in the two sexes, and touched on its prevalence in children of the Jewish race. He thought the diagnosis simpler in infants than in older children. He discussed the frequent association of umbilical hernia with other hernias. He laid great stress on the proper dieting of children suffering from this affection, and considered that phimosis does not play an active part in the production of hernia. He discussed the questions of exercises and mechanical forms of support and condemned the wool truss. He also spoke in detail with regard to different kinds of trusses, the proper instruction of the patient's parents or guardians, and the length of time during which a truss should be worn. He discountenanced operation prior to six years of age, except under pressing circumstances, and enumerated the cases in which operation is necessary. He preferred kangaroo tendon for sutures.

SECTION ON ANATOMY AND PHYSIOLOGY.

The address of the President, DR. J. J. CHARLES, was on

THE RECENT ADVANCES IN PHYSIOLOGY.

The speaker referred in detail to the numerous minor discoveries which have been made in this science during the past year or two. He gave great credit to English physiologists, who have of late years contributed their full share toward the advancement of the science, so that it is no longer necessary for a student to study physiology in Germany if he would place himself in the best position to obtain full command of his chosen specialty.

A discussion on

THE INTERACTION BETWEEN THE OVARIES AND THE MAMMARY GLANDS

was opened by MR. STANLEY BOYD. He showed that removal of both ovaries in some cases caused apparently a total disappearance of well-marked cancerous growths. The most marked case was one of a woman who, twenty-eight months after the operation, was apparently in perfect health and free from cancer. In other cases quoted the success was only partial; the growth at first underwent atrophy, and the patient's sufferings were for a time relieved, but this was later followed by recurrent growth in different parts, and finally by death. In other cases, especially those of "acute cancer" in young people, the operation seemed to have no marked effect. The administration, by the mouth, of the extract of thyroid gland appeared to produce uncertain results in some cases; the patient's condition was sometimes even made worse, while at other times there seemed to be slight improvement or no marked effects.

DR. AMAND ROUTH showed that ovulation proceeded normally after removal of both mammary glands, that lactation is unaffected by the removal of both ovaries during pregnancy, and that these combined facts establish fairly well the belief that there is no essential interaction between the ovaries and the mammary glands. From a case quoted it was shown that lactation was perfectly normal in a woman whose spinal cord was destroyed by an accident at the level of the fifth and sixth dorsal, proving that spinal conveyance of the pelvic influence is not the essential route. Further facts tend to show that lactation is due to some chemical change in the blood, and that this change is almost certainly in the uterus and not in the ovaries, and is practically an internal secretion.

MR. W. R. WILLIAMS, F.R.C.S., observed that cancer is known to subside under various states of constitution which reduce the general health to its lowest ebb.

MR. CANTLIE asserted that when the ovaries physiologically waste in a patient the subject of cancer the disease assumes a different state to that seen when the ovaries are normally active.

DR. PEMBREY referred to instances in which the ovaries of animals being diseased the development of the mammæ has been distinctly affected. MR. STANLEY BOYD, in replying, repudiated any suggestion that his operation is to be considered a "cancer cure."

SECTION ON PSYCHOLOGY.

The Presidential address was given by DR. DAVID NICOLSON, C.B., Lord Chancellor's Visitor in Lunacy, on the question,

CAN THE REPROACHABLE DIFFERENCES OF MEDICAL OPINION IN LUNACY CASES BE OBVIATED?

It was pointed out that the right estimate of conduct and of motives requires prolonged and careful observation, and this applies with peculiar force to judgments formed regarding cases of mental disease. The medico-psychologist has to use neurological methods—tests regarding reflexes, sensibility, etc.—as well as those belonging more properly to the domain of psychiatry. Particularly difficult to detect are cases of malingering or so-called feigned insanity, which often require prolonged watching and examination at an asylum before a definite conclusion can be reached. All medical men signing lunacy certificates should have asylum experience in the study, care, and treatment of insanity. It is a deplorable fact that owing to want of such knowledge and experience among the body of general practitioners cases of lunacy with suicidal and homicidal, or other dangerous impulses pass largely unrecognized in the community.

DR. SAVAGE opened a discussion on

THE TEMPORARY CARE OF INCIPIENT CASES OF INSANITY,

pointing out the desirability of extending some of the provisions of the proposed act of last year as regards the certification, readmission, and care (as single patients) of incipient lunatics.

DR. SEYMOUR TUKE said that it would be well to have every house and every person taking patients duly registered; and, further, it would be advisable that no person should be granted such permission who cannot show that he or she has some knowledge and experience of insanity and its treatment. The existing system which permits (or winks at) any one who choses to do so to take charge of patients of unsound mind is a scandal. Notification of certification should be the rule in all cases —every case should be brought under official cognizance.

DR. LIONEL WEATHERLY said that he had advocated for twenty years the view that supervision is as necessary in private houses receiving single patients as in public institutions. The great increase in recent years of the clandestine treatment of insanity in private care is a scandal, and he would welcome any legislation which provides for some supervision over these single cases. In very recent cases he feared some of our leading consultants were not altogether blameless.

DR. SHUTTLEWORTH opened a discussion on

THE TREATMENT OF EPILEPTICS AND IMBECILES.

He said that there is at present no provision for sane epileptics in England. In the United States such provisions are afforded by the Craig Colony, New York, and by similar institutions. The system is generally that of detached cottages for housing the patients, and the buildings are spread over a large area. Workshops and gardens, orchards, farms, etc., are provided for teaching and training in useful occupations and industries. An institution of such a kind would be a boon to the country.

DR. FLETCHER BEACH referred to the medical aspects of the question. He spoke well of the alkaline bromids

and of strontium bromid. The addition of liquor strychninæ in suitable cases prevents spinal-cord depression. Workmen liable to fits should receive 60 grs. of bromid on going to bed. In syphilitic cases the addition of the alkaline iodids is indicated. Errors of ocular refraction should be corrected if present. Open-air occupation and a diet in which nitrogenous food (meat, eggs) is reduced to a minimum should be the rule. All epileptics should be advised not to marry—emphatically.

Dr. Lloyd Andriezen referred to the importance of open-air occupation in farms and fields. The system of providing workshops not only for industrial training, but to make institutions for epileptics in a measure self-supporting is a step in the right direction. In the administration of bromids he had found the addition of a small quantity of syrup of the hypophosphites beneficial in averting muscular depression and feebleness of circulation. For several years he had tried a combination of antipyrin (5 gr.) and ammonium bromid (15 gr.) in cases of epilepsy, and found it beneficial in preventing apathy and stupor which patients would otherwise exhibit, and in promoting a degree of mental brightness and clearness.

Dr. Haig contributed a few remarks on the value of non-nitrogenous diet in epilepsy. He recommended the total disuse of meat, eggs and tea, and proposed a system of diet free from uric acid, which substance he looked upon as the primary agent in producing attacks of headache and mental dulness and depression, and even epilepsy. The diet recommended consists of 10 ounces of bread per diem, 12 ounces of vegetables and fruit, and about 2 ounces each of oatmeal, rice, milk, and cheese. Macaroni, potatoes, etc., can be taken in proportion to the wants of hunger and labor; and those patients who have been accustomed to eat much meat may be given in addition small quantities of protein and gluten.

Section on Pharmacology and Therapeutics.

Dr. Burney Yeo introduced the subject of

intestinal antiseptics.

He stated that they should be used to antagonize the evil effects of toxic agents, or, in other words, to prevent auto-intoxication. The scientific basis for the use of antiseptics rests on our knowledge of bacteria. Our aim should be to render the bacteria non-virulent. Morbid conditions calling for the use of antiseptics are gastric dilatation, duodenal indigestion, summer diarrhea, and remote affections of other organs. Dr. Yeo dealt with the use of sterilized water, mercurials, chlorin, bismuth salts, and carbolic acid, but recommended more especially menthol, thymol, and other volatile substances which are not absorbed by the stomach. Salol cannot be relied upon. In a large number of cases irrigation is also desirable.

Dr. Hugh Walsham read a paper, entitled

cases treated with erythrol tetranitrate.

He found its administration safest in the form of chocolate tablets. The patients treated were suffering from various forms of heart disease, from interstitial nephritis and from Raynaud's disease. Success was obtained in nearly every instance.

The President remarked that he had frequently used the drug and that the danger of explosion, with ordinary precautions, might be neglected. He had known sleeplessness of Bright's disease to be relieved by a single dose.

Section on Laryngology and Rhinology.

A discussion on

the diagnosis and treatment of chronic empyema of the frontal sinus

was opened on Thursday by Mr. Charters J. Symonds. He thought all were agreed upon two points: (1) The necessity for a free external opening in bad cases; (2) the usefulness of removing the anterior part of the middle turbinated body. Evidently, the weight of opinion favors intranasal methods. These may suffice for the simpler cases, but no force must ever be used. Opening the sinus from the nose is universally condemned as very dangerous. He does not attempt to remove all mucous membranes.

Section on Tropical Diseases.

Dr. George Thin opened the discussion on

psilosis or sprue: its relations (etiological and pathological) to other forms of tropical diarrhea, and its treatment.

He said that the disease is characterized by irregular and abnormal motions, there being, first, diarrhea, varying much in severity, frequency, and persistence; secondly, symptoms of disordered digestion, dyspepsia being always present; and, thirdly, progressive emaciation. He contested the opinion that sprue can arise in persons who have never been out of England. He drew attention to two types of the disease—one common in the Eastern Archipelago and the other common in India. In the former, mouth, tongue, and throat symptoms are prominent early; in the latter copious watery stools are the chief feature, and the mouth and tongue symptoms develop late or not at all. In the condition to which the term "white flux" or "diarrhea alba" is applied in India, mouth symptoms are usually synchronous with advanced malnutrition and emaciation. Dr. Thin said that of cases of sprue a third class develops in the Far East in elderly persons or in persons who have lived long in that region. Diarrhea is the initial sign, but very gradually the tongue grows raw and bare. A fourth class of cases is distinguishable in persons who have lived in the East and developed sprue after returning to reside in England. The pathology of sprue was summed up as a gradual atrophy of the organs of the body and a general emaciation. Atrophy of the mucous membrane of the stomach and intestine develops, and a sclerosis of the submucosa, but why the disease attacks the intestine is not known. Dr. Thin looked upon ulceration of the bowel as quite a secondary phenomenon. The etiology of sprue is unknown. It is associated with residence in certain parts of the world, and not in others. A specific poison, in all probability resident in the ileum, causes the disease.

DR. MANSON said that in his opinion sprue should be regarded not as one disease but as a variety of diseases, with a series of symptoms in common. In the tropics the abdominal organs are functionally very active, and suffer from subsequent exhaustion; hence their special liability to invasion by parasites and by various ailments. He regarded sprue in the tropics as pandemic, and had met with cases from the West Indies, India, and China. He recommended rest in bed, warmth, and simple diet. Milk and fruit (such as bananas) he held to be the staple diet, but considered that meat is indicated at times.

MR. JAMES CANTLIE read a paper on

SUPRAHEPATIC ABSCESS,

which he defined as a collection of pus between the layers of the broad ligament of the liver, having as boundaries the peritoneum circumferentially, the diaphram above, and liver below. The affection is not preceded by hepatitis, dysentery, or any other abdominal ailment. It is characterized by sudden onset, symptoms of fever, cough, and some respiratory distress. When allowed to pursue its course, the pus usually finds its way through the diaphragm and lung to a bronchus, from which the purulent matter is expectorated. He believed the disease to be due to chill, which causes a lymphangitis of the channels between the layers of the broad ligament. Dysentery plays no part in the etiology of the suprahepatic abscess. The pus is sterile; in other words, the suprahepatic abscess is the "sterile pus abscess" concerning which so much discussion has taken place. Local evidence of the disease is met with in the region of the right nipple, where, immediately internal to the nipple line, the highest point of an inverted saucer-shaped or cup-shaped area of dulness exists. The immediately superimposed part of the right lung suffers a fleeting congestion, which tends to obscure the area of the outline of the abscess, and may lead to mistakes in diagnosis and delay in treatment. Mr. Cantlie recommended early exploration, and, when pus is found, tapping by a large trocar and cannula, and the introduction of a drainage-tube of the largest size, in the manner recommended by Dr. Manson.

THERMIC FEVER OR SIRIASIS,

which has evoked much discussion lately, was dealt with by COLONEL KENNETH MACLEOD. There is no proof that any microbe peculiar to the disease exists, and Giles has shown that the injection of blood taken from persons suffering from heat-fever is not followed by any specific pathological change. All the organs in tropical climates which are called into overaction by the influence of heat soon tend to become played out. Hepatic excitement is followed by hepatic exhaustion, and so it is with the power of resisting heat. Long exposure to heat lessens the power of accommodation of the heat centers, and accounts for the decrease in the power of old tropical residents to withstand prolonged heat.

DR. SAMBON said that heat alone can not cause siriasis, and that there are many arguments in favor of the disease being due to a microbe. Many of the leading men in tropical pathology are favorable to such a conclusion, and Wood of Philadelphia has described a micro-organism.

MAJOR GILES, I.M.S., said that the geographical distribution of the disease argues in Dr. Sambon's favor. In proof of this he stated that the prevalence of sunstroke in many parts of the tropics is quite exceptional. As an example he cited the fact that troops in South Africa work in a temperature as high as in India, yet they are not subject to sunstroke.

DR. MANSON contended that though there is no direct proof that thermic fever is due to the toxic influences produced by a microbe, there is much in favor of such a theory. Microbes and parasites of many kinds develop only when a certain temperature is reached, and it seems, from a study of thermic fever, that at a certain given temperature a microbe is called into play which by its toxin produces the train of symptoms called siriasis.

A paper contributed by LIEUTENANT-COLONEL M'CARTIE, I.M.S., entitled

THE CAUSE AND PREVENTION OF HEAT APOPLEXY IN THE ARMY,

was read. The writer maintained that it is the uniform served out to the troops in India that is the main cause of the excess of sunstroke among them as compared with civilians. He showed that during an expedition the soldiers in their harassing and heavy uniform were knocked over by sunstroke while the coolies who accompanied them, although bearing heavier loads, did not suffer in the same manner. It is not only the amount of clothing, but its texture and its tight fit that places the soldier at a disadvantage. The coolies' clothing is loose and allows the skin free action so that there is a possibility of rapidly cooling the surface of the body.

SURGEON STALKARTT, R.N., read a paper on

BLACKWATER FEVER.

DR. SAMBON said that he considered blackwater fever to be a specific disease, that its malarial origin is improbable, and that both by its character and by its geographical distribution it presents all the features of a distinct disease. He entirely disagreed with Koch in his statement that it is the result of dosage by quinin.

DR. MANSON discussed the subject from a broad standpoint, and pointed out the arguments in favor of, and the arguments against the association of blackwater fever and malaria. Blackwater fever occurs in a limited geographical range; it does not occur at the season of the year in which malarial disease is most rife; the malarial parasite is not always found; and cases of blackwater fever have occurred within a short period after a tropical country has been reached, and before malaria could have acquired a marked hold on the system. On the other hand, blackwater fever occurs in highly malarial districts; the malarial parasites are often met with in the blood; the fever is most apt to occur in persons who have had many attacks of malarial fever and who have been exposed to the "climate" for three or more years.

CAPTAIN W. J. BUCHANAN, I.M.S., read a paper on

DYSENTERY AS A TERMINAL SYMPTOM OF DISEASE IN THE TROPICS.

From observation of a large number of cases, twenty-eight of which were recorded in detail in the paper, he showed that dystentery is very apt to supervene a few weeks before death, and to carry off the patient.

DR. MANSON said that Captain Buchanan's paper illustrated the power of healthy organs to resist the pernicious action. When the restraining influences which prevail during health are removed, the disease has full scope.

COLONEL MACLEOD said that dysentery is a frequent precursor of death in leper and lunatic asylums in India. He believed that when once dysentery prevails to a considerable extent in a dwelling it becomes infected, and that the infection is very difficult to get rid of.

REVIEWS.

RESPIRATORY EXERCISES IN THE TREATMENT OF DISEASE, notably of the heart, lungs, nervous and digestive systems. By HARRY CAMPBELL, M.D., B.S., London. Physician to the Northwest London Hospital, and to the Hospital for the Diseases of the Nervous System, Walbeck street. New York: William Wood & Co., 1899.

THE facts developed in this little volume may be summed up as follows: (1) there are several types of breathing—clavicular, lower costal, abdominal, etc.; (2) the character of the breathing determines a varying effect upon the circulation in the arteries, veins, and lymphatics in different parts of the body; (3) patients may be taught the exercise of the kinds of breathing, which, with or without passive motions and gymnastics of the trunk and extremities, are of value in the treatment of certain nervous, cardiac, and digestive disorders; (4) of special importance are respiratory exercises in the treatment of most chronic and some acute pulmonary lesions. In emphysema they maintain or restore pulmonary elasticity; in bronchitis and phthisis they determine salutary changes in blood-supply and blood-pressure.

The instructions for the employment of the exercises in these diseases are very meager; in fact we believe that the author has left out much that might have been said to good advantage.

TRAITÉ DE MEDICINE ET DE THERAPEUTIQUE PUBLIÉ. Sous la direction de MM. P. BROUARDEL AND A. GELBERT. Tome VI. Maladies du Cœur, des Arteres, de L'Aorte, des Veines, Du Systeme Lymphatique et Du Sang. Paris: J. B. Bailliere et Fils, 1899.

MOST of the articles in this volumeare by writers whose names are unfamiliar in America. The volume is, however, well up to the excellent standard that characterizes the preceding ones and is worthy of the ambitious purpose of the treatise to be a thoroughly up-to-date review of medicine.

The chapter on functional disorders of the heart is especially good. The digestive reflexes and the neurotic conditions generally that affect the heart rhythm, its rate and intensity, are well brought out. There is an illustration of the increased size of the heart and dulness to percussion just after a heavy meal that is of itself a striking lesson in the possibilites of mechanical stomachic interference with heart action.

Some of the French terms used in the book to describe the complications that develop in various organs as a consequence of a heart lesion are very picturesquely straightforward, for instance, the cardiac kidney, the cardiac liver, the cardiac stomach, the cardiac brain. They are impressive reminders of the complications so prone to occur in heart trouble, the real conditions that need treatment. Rupture of the heart is treated of at length. The accident is much more frequent than is usually supposed or could ever be imagined where autopsies are not made as a routine practice.

THERAPEUTIC HINTS.

Treatment of Variola.—

1. Local treatment.

For pain and itching of the early stage:

℞ Ac. carbolici cryst. } aa . . gr. xxx
Iodi }
Glycerini . . . . . Oi.

M. Sig. Brush over eruption 3 or 4 times a day.

To prevent pitting:

℞ Ol. picis liquidæ } aa . . . ℥ i
Vaselini carbolizat. }
Lanolini . . . . . ℥ iii.

Mix thoroughly. Apply to exposed parts 3 times a day. An air-tight coating is formed, which also aids in relieving pruritus.

2. General treatment.

For initial stage, give acetanilid, 1 to 5 grains every hour according to age of patient, to diminish temperature, induce perspiration, and help bring out eruption. Quinin is contraindicated as it does not lower temperature and does increase delirium. Mild purgatives are helpful. Diet: Milk, eggs.—*J. C. Slack.*

Anesthetic and Hemostatic Solution for Dental Work.—LEGRAND gives directions for the use of this solution which he states will render the extraction of teeth or roots entirely painless and prevent hemorrhage.

℞ Gelatini pur. . . . . gr. xxx
Sodii chloridi . . . . . gr. xii
Ac. carbolici cryst. . . . . gr. iss
Cocainæ hydrochlor. . . . . gr. v
B.-eucain hydrochlor. . . gr. xii
Aq. dest. . . . . q.s.ad. ℥ iii ʒ ii.

M. Sig. For hypodermic use.

Place a small tampon wet with the solution on the gum. In a few minutes begin to inject 6 to 10 minims of the warmed solution along both external and internal surfaces of the tooth. Insert the needle below the neck and pass it along toward the root, pressing in the needle as deeply as possible. Three minutes after completion of the injection the tooth can be pulled painlessly, and the blood which then fills the alveolar cavity will coagulate and prevent further loss of blood.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LXXV. NEW YORK, SATURDAY, SEPTEMBER 9, 1899. NO. 11.

ORIGINAL ARTICLES.

THE SPECIFIC CAUSE OF YELLOW FEVER. A REPLY TO DR. G. SANARELLI.

By WALTER REED, M.D.,
SURGEON, UNITED STATES ARMY,
AND
JAMES CARROLL, M.D.,
ACTING ASSISTANT-SURGEON, UNITED STATES ARMY.

WERE it not for the fact that the general practitioner of medicine in this country takes such a lively interest in all that pertains to the causation of yellow fever, and might construe our silence as an admission that we had followed faulty methods in our work, we would not at this time reply to the paper of G. Sanarelli, entitled "Some Observations and Controversial Remarks on the Specific Cause of Yellow Fever," which appeared in the MEDICAL NEWS under date of August 12, 1899. To those who are acquainted with the methods followed in the laboratories of the Army Medical Museum, we believe that we could well afford to leave this matter until such time as our completed observations might be given publication.

We pass by, therefore, as unworthy of comment, Sanarelli's insinuation that we could lend ourselves to the support of any personal controversy between himself and Surgeon-General Sternberg; and further, his advice that we should have "looked up for a moment some good treatise on bacteriology before attempting to launch such a paradox" as that bacillus icteroides should be considered to be a variety of the hog-cholera bacillus.

That our paper should partake somewhat of a controversial character, we very much regret, since we would have much preferred to publish our observations in full, so that our fellow-workers might be placed in possession of the complete details of our experimental work and thus be in a position to judge whether our methods had been good or faulty. But for the reason given at the commencement of this paper and because of the remarkable tone of Sanarelli's article, we must take up what we consider to be a somewhat unpleasant task.

Because we have recorded focal necroses in the liver of guinea-pigs and rabbits inoculated with bacillus icteroides (we might have mentioned necroses in the liver of dogs, which Sanarelli has quite overlooked); and since, in Sanarelli's opinion, we have failed to reproduce that degree of "acute steatosis" which he and others have recorded, we are designated as "victims to some deplorable neglect of technical precautions in the laboratory," and the conclusion is drawn "that a gross and deplorable error was made in their laboratory and that somehow the cultures of the two micro-organisms being experimented with got mixed for want of sufficient attention."

We are willing to admit that such a condition of affairs, as is implied in the latter part of this quotation, is possible in any laboratory; but in this connection we cannot refrain from paying our admiration to Sanarelli's mental acumen in arriving at this conclusion, since he must have realized that, if we had *not* "mixed the two micro-organisms," his claim for the discovery of the specific cause of yellow fever can no longer be sustained.

And here let us avow that we hailed with delight Sanarelli's announcement of the discovery of his bacillus icteroides as the specific agent of yellow fever and earnestly hoped that his work would be confirmed by other observers. When later directed by Surgeon-General Sternberg to carefully compare bacillus *x* with bacillus icteroides and report to him the results of our investigations we were only influenced by the desire to ascertain whether these were distinct bacilli, and if so, to see whether we could confirm Sanarelli's observations in the several animals. That we could be influenced in the slightest degree by Dr. Sternberg in arriving at our conclusions is a grave aspersion upon our reputation as scientific workers.

If it can be proved that we have "mixed" our cultures and hence arrived at incorrect conclusions, we will hasten to admit our mistake. Let us see whether we have been careless in our technical precautions, and hence have, by mistake, inoculated our animals with the bacillus of hog-cholera when we had intended to use bacillus icteroides.

In the first place, before proceeding to consider Sanarelli's criticisms of our work, we desire to state that the culture of bacillus icteroides with which we have made the majority of our observations, was obtained by Dr. Sternberg from Pasteur's laboratory. We are informed by Dr. Sternberg that the package containing this culture was opened by Professor Roux in his (Sternberg's) presence and the culture

handed to the latter. It was delivered to one of us by Dr. Sternberg on the 24th day of September, 1897, and bore the label of the Laboratory of Hygiene, University of Montevideo. We may remark that this culture was not in the shape of the ordinary stroke culture, but contained a number of well isolated colonies, such as would be obtained by inoculating an agar slant with a small drop of the blood of an infected animal. Several of the colonies on this agar slant showed the peculiar appearance of growth which Sanarelli considers as characteristic of bacillus icteroides. It was from one of these so-called characteristic colonies that we made our first transfer. Subsequent transplantations have been made by us at intervals of about four weeks, and have always been labeled "Bacillus Icteroides, Original." We have thus transplanted this original culture on agar, without transmission through animals, for a period of nearly two years. Like our other stock cultures, it has been kept in agar tubes provided with rubber caps and always in a dark closet.

In the second place, at the time that we began our investigations (September, 1897), no culture of the hog cholera bacillus was in our laboratory, nor did we procure a culture of this bacillus from the Bureau of Animal Industry until the following spring (May, 1898) about seven months after we had begun our work

We may be excused for particularizing somewhat in this connection in order to set ourselves right before those who are interested in this subject.

Let us then state that the hog cholera bacillus was one with which neither of us was acquainted, except as to some of its most prominent morphological and biological features, such as size, motility, growth in milk, and in the three sugars; but we had not witnessed its pathological effects in the smaller animals. We had more than once commented on the fact that its action on litmus milk, and in the three sugars was similar to that of bacillus icteroides; but as we were not prepared at that time to look upon bacillus choleræ suis as a secondary invader in human beings, we did not follow up the subject further.

During the month of February, 1898, we had ascertained that the blood-serum of a dog partially immunized against bacillus icteroides, although exercising decided agglutinative action upon the latter, was negative as regards the typhoid bacillus and bacillus coli communis, except in low dilutions. At this time our observations were almost completely interrupted by our duties with the class of the Army Medical School. We had scarcely resumed our work when we were honored with a visit from Dr. Theobald Smith, formerly of the Bureau of Animal Industry, and who did all of the bacteriological work recorded in the "Report on Hog Cholera; Its History, Nature, and Treatment," to whose instructive pages Dr. Sanarelli has so courteously invited our attention. We communicated to Dr. Smith the fact that bacillus *x* (Sternberg) when injected into the circulation of dogs would cause the same general symptoms, and the same extensive hemorrhagic lesions in the stomach and intestine as was produced by bacillus icteroides, and hence that these lesions were not confined to the action of the latter bacillus. Dr. Smith then remarked that in reading Sanarelli's various articles, *he was continually reminded of the hog-cholera bacillus.*

When further told by us that bacillus icteroides produced multiple necroses in the liver of guinea-pigs, he remarked that he was of the opinion *that bacillus icteroides would yet be placed in the hog-cholera group.* Fortified by this expression of opinion by one, than whom no one is more conversant with the hog-cholera bacillus or its pathological action, we for the first time proceeded to procure a culture of bacillus choleræ suis, and to test the action of our dog's serum, with the result already given in our preliminary note. As we had *already*, many times, obtained these focal necroses in guinea-pigs with bacillus icteroides, how could we have "mixed the two micro-organisms?" We could scarcely have mixed what we did not have in our possession. If, as Sanarelli has stated, these "focal necroses are entirely specific for hog-cholera," we had already proven by the production of these that bacillus icteroides was a variety of the hog-cholera bacillus. It is very important to note that cultures taken from these animals gave, in about thirty per cent., colonies similar in all respects to those described by Sanarelli as characteristic of bacillus icteroides.

Turning now to Sanarelli's criticisms of our work, these may be stated as follows:

First. The marked difference in growth on potato of his bacillus and bacillus choleræ suis.

Second. That the toxin of his bacillus resists a temperature of 100° C., while that of the hog-cholera bacillus undergoes modification as low as 60° C., and is entirely destroyed at 100° C. Sanarelli here quotes from Selander's observations.

Third. Dissimilarity of growth in gelatin plates of these two bacilli.

Fourth. That while the hog-cholera bacillus produces a large number of foci of coagulation necrosis (the organ is not stated), these do not occur in animals inoculated with bacillus icteroides.

Fifth. That we have failed to produce acute steatosis, or fatty degeneration of the liver in dogs injected with his bacillus.

As regards the difference in growth on potato

Sanarelli says, "it is sufficient to recall that the bacillus of Salmon forms on potato a luxurious brownish-colored culture somewhat like that of Mauve, while my bacillus icteroides develops on potato completely without color and is scarcely visible."

Salmon and Smith,[1] in their report, implied neglect of which on our part to even casually glance at, has occasioned Sanarelli so much apparent regret, state as follows: "growth on boiled potato when at 95° F., appears as a faint straw-colored deposit within twenty-four hours after inoculation. At 20° C. or 25° C., it appears one or two days later. It slowly spreads in all directions as a layer of perceptible thickness. The color changes to a dark brick-red, or *may remain whitish* (italics our own). In general the growth is darker the more rapidly the potato dries up."

Smith and Moore,[2] in describing the growth of several varieties of the hog-cholera bacillus, state "that there may be slight variations in the depth of color of the growth on potato due to variations in the potatoes used. Now and then potatoes are encountered on which no growth appears. The surface assumes a glistening appearance, but multiplication perceptible to the eye does not take place."

Welch,[3] describing the growth of the hog-cholera bacillus, says: "the growth on potato assumes generally a brownish or yellowish tint, *but it may be white* and *sometimes is indistinct* (italics our own), although microscopically the growth is abundant."

Our own observations show that the hog-cholera bacillus, when transplanted on potato grows, as a rule, as a moist straw-colored or brownish layer spreading over the greater part of the surface of the medium; but that exceptionally it presents a moist, almost colorless layer. Cover-slips from this moist, almost colorless layer show that a marked multiplication of the bacilli has taken place.

It will thus be seen that the growth of the hog-cholera bacillus on potato is variable, and that it does not always produce "a luxurious brownish colored growth," as claimed by Sanarelli.

Our experience with the growth of bacillus icteroides on potato is at variance with that given by Sanarelli. Both of us promptly transferred to various media the original bacillus icteroides turned over to us by Dr. Sternberg on September 24, 1897. As regards the growth on potato, we quote from our notes made on September 29th, 1897, as follows: Dr. Carroll, "a moist brownish growth." Dr. Reed, "grows less rapidly than bacillus *x*, giving a moist, thin, brownish layer, which spreads over the surface of the medium." These were duplicate observations made independently of each other.

Our subsequent observations have shown that bacillus icteroides on potato may grow as a colorless moist layer, or as a faint yellowish layer, or that it may show a decided brownish color.

A. Agramonte,[1] who spent some months in this laboratory comparing a bacillus which he had obtained from yellow-fever cadavers at Santiago, Cuba, during the summer of 1898, with bacillus icteroides, could find no difference between these. He says as regards the growth of this bacillus: "Potato cultures for twenty-four hours at 39° C. gave an abundant pale-cream, almost colorless growth; when compared side by side with others made of bacillus icteroides it was impossible to differentiate them. At the end of a week the cultures remained of the same color; while some of bacillus icteroides had taken on a *brownish* tinge (italics our own), others remained the same.

All of which goes to show that bacillus icteroides does not always grow on potato as a colorless, scarcely visible layer, as claimed by Sanarelli, and hence that he cannot safely base a differentiation on this account between his bacillus and bacillus choleræ suis. It would be well if Sanarelli would recall our experience with the typhoid bacillus. As with that bacillus, so with bacillus icteroides, it may or may not grow on potato as a colorless layer.

With reference to the claim of Sanarelli that the toxin of his bacillus will resist a temperature of 100° C., while that of the bacillus of hog-cholera undergoes modification as low as 60° C., and is entirely destroyed at 100° C., we have no observations of our own to record. We propose to show, however, that his statement concerning the supposed effect of certain temperatures on the toxin of the bacillus choleræ suis, which he quotes from Selander, is entitled to no credence whatever. Indeed, we consider Sanarelli's reference to the work of Selander and Metchnikoff[2] as particularly unfortunate, since subsequent observations have conclusively demonstrated that at that time, 1890–92, neither Selander nor Metchnikoff were working with the hog-cholera bacillus!

We almost feel like suggesting to our distinguished critic that he should follow the advice which he seems so willing to give to others, and spend a brief time in consulting the literature on this subject.

Referring to Selander's investigations, Welch and Clement[3] say: "We wish, however, in this connec-

[2] *Annals de l'Institut Pasteur*, 1890–92.
[3] "Hog Cholera and Swine Plague," Proceedings First Veterinary Congress of America, Chicago, 1893.

tion, to express our conviction that the organism described by Selander in 1890, and probably also that by Metchnikoff later, as the hog-cholera (or swine-pest) bacillus, is not identical with the genuine hog-cholera bacillus as we know it in this country." After recording their inability to confirm the experiments of Selander in increasing the virulence of the supposed hog-cholera bacillus, they say: "Whatever this organism of Selander may have been, we feel convinced that it was not our hog-cholera bacillus, and we base this conclusion upon the results of his experiments in Pasteur's Institute, as published, and upon our experience with the cultures with which he kindly supplied us. . . . We believe Metchnikoff's hog-cholera microbe to be one of the hemorrhagic septicemia bacilli, possibly the swine-plague or schweine-seuche bacillus."

This opinion expressed by Welch and Clement was subsequently proven to be correct by Smith and Moore,[1] to whom Metchnikoff, having confirmed the observations of Selander in increasing the virulence of the supposed hog-cholera bacillus sent the blood of a guinea-pig inoculated with the bacteria in a sealed glass tube. These writers state that "cultivated on various substrata they presented all the characters of swine-plague bacteria as found in this country." Certainly we have not claimed any affinity between the swine-plague bacillus and bacillus icteroides.

Not only does Sanarelli, in quoting from the work of Selander concerning the effect of varying temperatures upon the toxin of Selander's bacillus, confound the bacillus of swine-plague with the bacillus of hog-cholera. but he also displays the most astonishing want of acquaintance with the biological characters of the last-named bacillus. He says: "We may recall, besides, that colonies of the two forms of bacilli (bacillus icteroides and bacillus choleræ suis) on gelatin plates are as readily differentiable. even at first sight, as it is possible for bacilli to be."

On the contrary, we wish to state that plated, side by side, in gelatin, we have been unable to detect any differences in the colonies of these two bacilli with the naked eye, and that it is only by means of the microscope that faint differences can, as a rule, be made out, such as a slightly increased radiation in the colonies of bacilli icteroides, as compared with those of bacillus choleræ suis. We are, therefore, constrained to the opinion that Dr. Sanarelli has never plated on gelatin the genuine hog-cholera bacillus, such as we know it in this country.

Referring to the focal necroses found by ourselves in the liver of guinea-pigs and rabbits inoculated with bacillus icteroides, Sanarelli says: "I am very much surprised that Reed and Carroll should have found this lesion, and should have betrayed seemingly good faith in describing it so carefully, without realizing that the lesion is entirely specific to hog-cholera and limited to that affection, and is completely unknown in infections with bacillus icteroides."

We can pass by the discourteous part of the foregoing sentence; but we must confess that even had we not succeeded many times in producing these focal necroses in the liver of pigs and rabbits with bacillus icteroides, we were not prepared for the statement that this lesion was "entirely specific to hog-cholera and limited to that affection;" especially since Blachstein[1] had succeeded in producing this lesion in the liver of rabbits by the intravenous injection of bacillus coli communis and bacillus typhi abdominalis; and since, moreover, one of us (Reed[2]) working in Welch's laboratory, had caused the same lesion by injecting cultures of the typhoid bacillus into the mesenteric vein of rabbits.

Blachstein, speaking of the lesions due to bacillus coli communis, says: "The more striking and constant lesions, those most characteristic of the affection are in the bile and liver." Further he says: "only one or two such areas may be noticed, or they may occur in large numbers. . . . These areas occur both on the surface and in the depth of the liver. . . . On microscopical section these areas are found to be places where the liver cells have undergone necrosis." He adds: "These necrotic and inflammatory changes appear to be of essentially the same nature as have been observed after ligation of the common bile duct (Foá, Salvioli, Pick, and others), and occur in other infectious processes, such as after inoculation with typhoid bacilli, and with hog-cholera and schweine-pest bacilli."

Indeed, scattered areas of coagulation necrosis in the livers of these animals have been produced by other bacteria, and notably by such toxalbumens as abrin and ricin, in the hands of Flexner,[3] and we know, as stated by the latter, the close relationship existing between these bodies and certain bacterial toxins.

Again we ask, can Dr. Sanarelli be ignorant of the rich literature relating to the production of multiple focal necroses in the liver of guinea-pigs, rabbits, kittens, etc., by the bacillus diphtheriæ and its toxins? Indeed, in limiting focal necroses in the livers of guinea-pigs and rabbits to the agency of

one particular bacterium, Sanarelli displays profound ignorance of the pathology of coagulation necrosis.

Turning to our statement that these lesions are caused by inoculation with bacillus icteroides, we invite attention to the fact that Agramonte,[1] to whom we communicated our observations, obtained the same necroses in pigs injected with a bacillus obtained from yellow-fever cadavers (33 per cent.) at Santiago, and which he identified as bacillus icteroides (Sanarelli). We note also that De Lacerda and Ramos[2] record the finding of "scattered yellow points" (*avec des points jaunes disséminès*) in the liver of one rabbit out of four inoculated with bacillus icteroides and which died on the second day. They say nothing about the microscopic examination of these scattered yellow points.

We have failed to find, as a rule, necroses in the livers of animals dying earlier than the fourth day, although we have generally found them between the fourth and ninth day after inoculation, especially prominent in the livers of guinea-pigs. Our earliest recorded observation was made on November 13, 1897, upon autopsying guinea-pig No. 456, dead on the fourth day after receiving 1 c.c. of a 20-hour bouillon-culture of bacillus icteroides. Concerning the liver, we note: "Organ pale; some recent adhesions, numerous small punctiform areas, yellowish white in color, to be seen under capsule."

With regard to the several observers cited by Sanarelli as in opposition to our findings, we have been unable to obtain the articles written by some of these and hence cannot state just what lesions they did find in the livers of the inoculated animals. Of those accessible to us, we find that Domennica della Rovera[3] states the following as the result of his infection of guinea-pigs with bacillus icteroides: "My experiments have demonstrated as a new finding in the liver, foci of small cells (focolai parvi cellulari) situated in the midst of the lobules; the protoplasm of the liver-cells appear very granular, the nuclei discolored and feebly stained, as well as the nuclei of the cells lining the biliary canals and capillaries." This description of Rovera agrees very well with what we have found microscopically, except that we also find larger foci, whose capillaries are crowded with polymorphonuclear leucocytes, and whose cells stain brightly with eosin, especially toward the more central parts of the area. Sometimes we find an entire lobule the seat of coagulation necrosis. This quotation further shows the accuracy with which Della Rovera has made his observations, and completely refutes the position taken by Sanarelli, *viz.:* that focal necroses are never found in the livers of animals inoculated with bacillus icteroides. Rovera[1] also says concerning lesions found in the livers of rabbits: "I also saw foci of small cells, situated within the lobules, such as I have already recorded for guinea-pigs."

In view of the foregoing observations comfirming our findings as regards the agency of bacillus icteroides in producing focal necroses in the liver of of guinea pigs and rabbits, we are constained to say that Dr. Sanarelli in emphasizing the specific character of these necroses for the hog-cholera bacillus, again shows a surprisingly limited knowledge of the work which has been recorded in this line. We are quite willing to admit, however, that these necroses are probably more abundantly produced by the hog-cholera bacillus and its varieties, such as bacillus icteroides, than by other bacteria.

This brings us to Sanarelli's fifth criticism of our results, *viz.:* that we "did not succeed in reproducing the acute steatosis, fatty degeneration of the liver in dogs that was always so prominent a feature in my own observations as well as those of Foà" and several other investigators whose names we here omit.

We have endeavored to extract from the literature, as far as the Library of the Surgeon-General's Office would permit, the experiments made upon dogs by various observers, but have not been able to find definite data except as regards the experiments of Sanarelli,[2] De Lacerda and Ramos,[3] to which we add our own results.

We submit these in the following table:

It will be seen that there are eight (8) observations by Sanarelli; twelve (12) by De Lacerda and Ramos, and seven (7) by Reed and Carroll, making a total of twenty-seven (27). Of these, six (6) dogs recovered, leaving twenty-one (21) that died as the result of the intravenous inoculation of the cultures or toxin of bacillus icteroides, or both of these. In one instance, the toxin was injected both intravenously and into the substance of the liver. Omitting one dog, which was not autopsied, we have twenty (20) fatal results, with fatty changes in liver recorded in thirteen (13), or sixty-five per cent. Of these, one, reported by Sanarelli (No. 3), died within three hours and forty minutes after receipt of the injection, and "showed that the hepatic cells were already rich in fat drops." He does not state that there was any fatty degeneration present, and we can well believe that such was not the case.

Injection of Dogs with Bacillus Icteroides.

Observer.	No.	Quantity received.	Result.	Remarks.
Sanarelli....	1	10 c.c. of a 24-hour bouillon culture, intravenously.	Recovered.	
"	2	Agar culture diluted with 1 c.c. of a bouillon culture, intravenously.	Died during the same night.	Liver congested, but no fatty degeneration.
"	3	Agar culture diluted with 1 c.c. of a bouillon culture, intravenously.	Died in 3 hours and 40 minutes.	Liver shows numerous yellowish spots. Fresh sections in osmic show the hepatic cells already rich in fat drops.
"	4	5 c.c. of a bouillon culture, intravenously.	Died on 16th day.	Intense fatty degeneration of liver.
"	5	Agar culture diluted with bouillon—quantity not stated, intravenously.	Died during the same night.	Liver pale with zones of fatty degeneration.
"	6	2 c.c. of a bouillon culture, intravenously.	Died on 19th day.	Marked fatty degeneration of liver.
"	7	2 c.c. of a bouillon culture, intravenously.	Died on 8th day.	Fatty degeneration of liver.
"	8	5 c.c. of a bouillon culture, intravenously.	Died on 10th day.	Marked fatty degeneration of liver.
De Lacerda and Ramos.	1	1 c.c. of an agar culture diluted with 10 c.c. of sterilized water, intravenously.	Died during the same day.	No change in liver.
" " "	2	10 c.c. of an agar culture diluted with sterilized water, intravenously.	Recovered.	
" " "	3	20 c.c. of a bouillon culture into liver.	Recovered.	
" " "	4	20 c.c. of a bouillon culture 2 days old, intravenously.	Died on 19th day.	No autopsy.
" " "	5	35 c.c. of a bouillon culture 3 days old, intravenously.	Recovered.	
" " "	6	35 c.c. of a bouillon culture 1 day old, intravenously.	Died in 16 hours.	No trace of fatty degeneration.
" " "	7	18 c.c. of a bouillon culture 2 days old, and 38 days later 60 c.c. of toxin, both intravenously.	Died in about 8 hours after the 2nd injection.	Fatty degeneration of liver.
" " "	8	20 c.c. of a bouillon culture and 10 c.c. of the toxin, intravenously.	Died in 24 hours.	Liver and kidney of a blackish color. Nothing said of fatty generation.
" " "	9	60 c.c. of the toxin, intravenously.	Died during the same night.	Intense congestion of all organs. No fatty degeneration.
" " "	10	20 c.c. of the toxin, intravenously, and 20 c.c. into the liver.	Died in 24 hours.	Fatty degeneration of liver, kidneys, and heart.
" " "	11	70 c.c. of the toxin, intravenously.	Died at 1 o'clock of the same night.	Fatty degeneration of liver.
" " "	12	50 c.c. of the toxin, intravenously.	Died on 7th day.	Disseminated points of fatty degeneration but little advanced.
Reed and Carroll.....	1	5 c.c. of a 24-hour bouillon culture, intravenously, Sept. 24, 1897.	Died on 9th day.	Necroses in liver. Moderate fatty degeneration.
" " "	2	5 c.c. of a 24-hour bouillon culture, Nov. 16, 1897, and a second injection of 5 c.c. 14 days later, both intravenously.	Died in 28 minutes after second injection.	Slight fatty degeneration of liver.
" " "	3	2½ c.c. of a 24-hour bouillon culture, intravenously, Dec. 13, 1897.	Died on 9th day.	Marked fatty degeneration of liver.
" " "	4	5 c.c. of a 24-hour bouillon culture, intravenously, Feb. 9, 1898.	Recovered.	
" " "	5	5 c.c. of a 24-hour bouillon culture, intravenously, March 17, 1898.	Died in 52 hours.	Necroses in liver. No fatty degeneration.
" " "	6	5 c.c. of a 24-hour bouillon culture, intravenously, July 1, 1898.	Died in 16 hours.	Necroses in liver. No fatty degeneration.
" " "	7	5 c.c. of a 24-hour bouillon culture, intravenously, July 1, 1898.	Recovered.	

What he found in this liver may readily be found in the normal hepatic cells of dogs in a good condition of health and nutrition. We would, therefore, exclude this case as well as the case (No. 12) recorded by De Lacerda and Ramos, in which they found "disseminated points of fatty degeneration, but little advanced," in the liver. No results of the microscopic examination is given in this case to show what the true character of the "disseminated points" was, whether fatty or necrotic, and since it is not characteristic of fatty degeneration of the liver that it should be found in "disseminated points," we feel justified in also omitting this case. We will not do so, however, in order that we may not be accused of unfairness.

We thus find twelve (12) positive results against eight (8) negative results in dogs injected with bacillus icteroides. Of the positive results five (5) are recorded by Sanarelli in seven (7) animals that died (71.3 per cent.); four (4) by De Lacerda and Ramos in eight (8) dogs autopsied (50 per cent.); and three (3) by Reed and Carroll in five (5) deaths (60 per cent.). It will be seen that the percentage of cases showing fatty degeneration is highest in Sanarelli's experiments, due probable to the fact that his dogs lived longer, but that the percentage reported by De Lacerda and Ramos is less than that reported by ourselves. Since De Lacerda and Ramos are authorities quoted as sustaining Sanarelli in his observations concerning the frequent occurrence of fatty degeneration in dogs injected with bacillus icteroides, and since we have obtained this change in even a larger percentage of cases, it naturally follows that Sanarelli, in criticising us for our failure to produce fatty degeneration in the liver of dogs, was speaking as usual without any knowledge of the true facts, just as we have already pointed out that he has done in the matter of Selander's observations, and in the absurd statement that necroses in the liver of guinea-pigs and rabbits "are entirely specific for hog-cholera!" True we did state, and we wish here to repeat, that, with one exception hereafter to be given, the fatty change found in the liver of these dogs is not comparable to that found in the liver of human beings who have died of yellow fever, and we may add that there is an almost entire absence of that necroses of individual liver cells which is so prominent a feature in the human liver.

Sanarelli speaks as if yellow fever were the only condition in which fat is found in the liver cells. It is hardly necessary to remark that it may be present in considerable quantity in the livers of comparatively healthy individuals. Steatosis may mean little or much; it does not necessarily imply degeneration. Pathologists well know that in yellow fever the change that takes place in the liver is essentially one of *degeneration and necrosis*, in which the hepatic cells appear as denucleated bodies distended with minute fat-droplets and containing only a small amount of protoplasmic débris, or as somewhat refractive bodies, which stain brightly with eosin. Their outlines are very much distorted and the normal beam-work arrangement is no longer seen. Sanarelli's illustrations in Plate 10, Fig. 5, *Il Policlinico*, Nos. 16 and 17, 1897, prove that this degenerative and necrotic condition was not present in the livers of human beings inoculated with the toxin of his bacillus. In his section of dog's liver the arrangement of the liver cells is perfectly preserved, their nuclei stain well, and there is only a moderate deposition of fat in the cell protoplasm.

In connection with the production of fatty degeneration of the liver of dogs injected with bacillus icteroides, we desire to invite attention to the comparative degree of this change found in the case of dogs 531 and 928 of our series of experiments.

Dog No. 531, weight 17 pounds, was originally inoculated on February 9, 1898 with 5 c. cm. of a bouillon-culture of bacillus icteroides, from which he recovered. He was then subjected to intravenous injections of increasing doses until he was able to bear injections of 150 c. cm., of a bouillon-culture of this bacillus. On July 20, 1898, the animal had received 150 c.cm. of the culture, and died a few hours after the injection of the same quantity on July 29th. Thus this dog had received during a period of five (5) months and twenty (20) days, 1042½ c. cm. of a bouillon-culture of bacillus icteroides; yet at autopsy the liver was found to contain only a moderate amount of fat, and upon microscopic examination but slight fatty degeneration of the hepatic cells was to be seen.

On the contrary, dog 928, weight 19 pounds, was injected with cultures of the bacillus choleræ suis for the purpose of immunization, and received a total of 170 c.cm. during a period of four (4) months and five (5) days. The largest dose was 50 c.cm. injected on July 19, 1899, from which the animal died thirty-six hours later. At autopsy the liver was seen to be quite light in color, and upon microscopic examination the hepatic cells were found to be not only the seat of advanced fatty degeneration, but there were, also, to be seen many necrotic liver cells. Sections of this liver, indeed, show a stage of fatty degeneration and necrosis closely approaching that of yellow fever in human beings, and yet this animal was injected with bacillus choleræ suis! Or did we here again commit the deplorable error of "mixing the two micro-organisms"? Rather would we say that the important determining factor

in producing this fatty change was the difference in resistance of these dogs, and was not dependent on the particular variety of the hog-cholera bacillus with which we had injected them.

We observe, with some surprise, that Sanarelli does not comment on the remarkable agglutinative reaction which icteroides serum (supplied to us from Brazil, and presumably from animals inoculated with pure cultures of bacillus icteroides), exerts toward the hog-cholera bacillus. The scientific fact alone, *viz.*, that this serum diluted 100,000 times should arrest the motility and agglutinate another bacillus, should, we think, have momentarily attracted his attention; or is it possible that we here again got our cultures "mixed" and were really subjecting bacillus icteroides to the action of its own serum? Nor does he appear to have been impressed with the fact that the hog-cholera bacillus should so completely reproduce in dogs, not only the clinical picture of vomiting, rectal tenesmus, and profound prostration, but also death with extensive hemorrhagic changes in the stomach and intestines. We trust, however, that he will later procure a culture of the bacillus choleræ suis and give us the result of his observations with it on various animals. In the meanwhile, we beg to observe that Agramonte,[1] working in this laboratory for a period of four months, was unable to detect any differences between the "mixed" culture with which we, unwittingly, supplied him, and a bacillus which he had recovered in Cuba from yellow-fever cadavers, and which he identified as bacillus icteroides (Sanarelli).

Concerning the statement made by us in our preliminary note that bacillus icteroides and bacillus choleræ suis both resisted extremely low temperatures, we had not intended to "set this down as one of the characteristics of bacteria by which they might be recognized," since we did not know any bacterium that would not withstand low temperatures. We were only dealing with *bacillus icteroides as the supposed specific cause of yellow fever*, and since by a natural law the specific agent of this disease is arrested and destroyed by a temperature less protracted, and considerably less in degree, than the temperature required to destroy bacillus icteroides, we were justified in emphasizing this fact. We leave, however, to F. G. Novy, the easy task of answering this part of Sanarelli's article.

At the time we began our experiments with feeding bacillus icteroides to young hogs we were well aware that every precaution should be taken to avoid error in experiments on these animals, as emphasized by Welch and Clement.[2]

[1] *Centralblatt fur Bacteriologie*, etc., Band xxv, No. 18–19, 1899.
[2] Proceedings First Veterinary Congress of America, Chicago, 1893.

Our first experiment was made in a room where a dog had already died some weeks before from the intravenous injection of bacillus choleræ suis. On this account we did not attach too much importance to this observation. We proceeded at once, however, to procure a second-story room with cemented floor which had never been used for animal experimentation. We had it thoroughly wiped out with a disinfectant solution; we also covered the windows with mosquito-netting in order to prevent the ingress of flies. A new broom and mop were provided for this room. We placed therein four new wooden boxes, and in each of these we put a young hog on April 6, 1899. These animals had been purchased in open market, and were fat and healthy in appearance. April 8th, after withholding food for twenty-four hours, two of these pigs were fed with a twenty-four-hour-bouillon culture of "bacillus icteroides, original," passed through one guinea-pig for the purpose of ascertaining whether the bacillus grown on agar for a period of seventeen months was still virulent or not. On April 10th, 1899, the remaining two pigs were fed, under like circumstances and with a culture of bacillus icteroides having the same source. The culture of bacillus icteroides was in each case mixed with a small quantity of milk brought directly from the dealer. The temperature of the hogs was taken both before and after feeding, and we were careful to have the thermometer placed in a disinfectant solution immediately after being used. The hands of the attendant were also carefully disinfected on each occasion. Under these conditions, and with these precautions, the four animals promptly sickened and died, as shown in the following table:

Careful cultures were taken in each case from the several organs, the blood, bile, and mesenteric glands. From the liver in one case, and from the mesenteric glands in all other cases, colonies of a small, quite motile bacillus were obtained. This babillus was promptly agglutinated by high dilutions of Sanarelli's serum. From the other sources cultures were negative.

Now we think that looking at these experiments critically, there were two chances for error to have crept in; but not through lack of technical precautions or neglect on our part. In the first place, having injected the guinea-pig with "bacillus icteroides, original," we might have recovered the hog-cholera bacillus from his blood and organs, but this hardly seems probable. Our cultures were pure from this guinea-pig, and we have every reason to believe that we recovered bacillus icteroides. In the second place, as we only kept our young hogs for a few days before feeding them the culture, we

YOUNG HOGS FED WITH BACILLUS ICTEROIDES.

No.	Date.	Quantity.	Result.	Lesions.	Remarks.
976	Apr. 8, '99.	25 c.c. 24-hour culture.	Died on 9th day.	Diphtheritis of stomach and large intestine.	Diarrhea and fever April 10th, with thin, pea-soup stools. Weakness of hind extremities.
977	Apr. 8, '99.	15 c.c. 24-hour culture.	Died on 6th day.	Ulcers on lips; hyperemia of fundus of stomach; ulcerated Peyers patches; follicular ulcers in large intestine with cork-lining exudate.	Diarrhea and fever, beginning April 10th. Emaciation; loss of strength in hind legs.
978	Apr. 10, '99	20 c.c. 24-hour culture.	Died in 7 days.	Congestion and ulceration of mucosa of stomach. Ulceration and diphtheritis of cecum and colon.	Diarrhea April 11th and succeeding days. Emaciation. Loss of strength in hind extremities.
979	Apr. 10, '99.	15 c.c. 24-hour culture.	Died in 12 days.	Erosions on tongue. Diphtheritis of stomach and esophagus. Ulcers in stomach, small intestine, and cecum. Numerous small circumscribed thickenings in submucous layer of large intestine. The centers of some of these already undergoing necrosis.	Same clinical symptoms, beginning on April 12th.

cannot say that some one of these hogs may not already have been infected with the hog-cholera bacillus. They were bought in an open market, and we kept no controls for these first experiments, not being able to obtain pigs from the same litter. But admitting this chance for error, we can hardly believe that *all* of these hogs were already so badly infected with the hog-cholera bacillus that they should die within twelve days from the feeding, and that the symptoms of illness, such as diarrhea and loss of appetite, should have so promptly appeared after the inoculation with bacillus icteroides. If the hog-cholera bacillus were present in one, it was present in all, and it is remarkable that the disease should have run such an acute course after natural infection. We are informed by the dealer from whom these pigs were purchased that they had been in his possession for about a week when sold to us. He also has stated to us that during the present year, although retaining his hogs for periods varying from a few days to several weeks, he has not had any pig sicken or die on his hands.

We think, therefore, that we were quite justified, as the result of these experiments, in expressing the opinion that bacillus icteroides was a variety of the hog-cholera bacillus. We may state that nothing has occurred since the publication of our preliminary note to cause us to change this opinion; but that our subsequent results, such as the immunization of guinea-pigs with gradually increasing doses of the dead culture of bacillus icteroides against a fatal dose of the hog-cholera bacillus, and securing the same result by injections of the dead cultures of the latter bacillus against a fatal dose of bacillus icteroides, have rather confirmed us in that opinion.

We have also been permitted to study sections of the liver from the case of a soldier who died in Havana during the present year, and from the microscopical findings we are strengthened in the belief that bacillus icteroides should be considered as a secondary invader. From the blood of this case during life, bacillus icteroides was recovered both by the members of the Havana Commission and by A. Agramonte.[1] This bacillus was also obtained on cultures after death by the same observers. It is important to note, however, that from the spleen, after death, the typhoid bacillus was also obtained by Agramonte. Careful study of sections of the liver in this case shows an entire absence of fatty degeneration, while many areas of necrosis, such as characterize the liver of typhoid fever, are to be plainly seen. In other words, bacillus icteroides, though present during life in this patient's circulation, failed to bring about that "acute steatosis" upon which Sanarelli lays so much stress.

We hope, at an early date, to present our complete report to Surgeon-General Sternberg.

Smallpox at Niagara, Falls.—The spread of smallpox at Niagara Falls, New York, continues. Two new cases were reported on September 1st. The disease gained a foothold largely because cases of smallpox were diagnosed as chicken-pox.

[1] *Centralblatt für Bacteriologie*, etc., Band xxv, No. 18–19. 1899.

CARDIO-ESOPHAGEAL GUSH AND CLICK.[1]

By R. G. CURTIN, M.D.,
OF PHILADELPHIA.

In studying the sounds heard in and around the heart I have observed two a description of which I have not been able to find in the literature coming under my eye. I have every reason to think that they are extra-pericardial and, furthermore, I am quite sure that they are esophageal. In this paper you will be introduced to these two sounds, both of which are synchronous with the action of the heart; and from their many points of similarity I think they may be studied together. I will call them the cardio-esophageal gush and click. A study of the histories of the two classes, with their two sounds, will be the best way to introduce the subject.

In 1894 a girl, nineteen years old, called at my office, saying that she had a queer noise which a doctor had told her was a heart murmur that he could hear without applying the ear to the chest. She informed me that it was not so loud that day, for she could not hear it. I listened to her chest and found a mild, double, mitral murmur, with evidence of some hypertrophy. She then complained of dyspeptic symptoms only. I told her to return to me if the sound came back, which she did next day. I could then hear a sound with the action of the heart, which was then excited; and, on withdrawing my ear one yard away from the chest, I could hear the sound, which was before or early in the systole, when her mouth was open. When she closed her mouth the sound was very perceptibly deadened. It continued when her breath was held. On applying the ear to the chest the sound was subdued, being less distinct than when the ear was held in front of the open mouth. It sounded like a short gush of air from the throat modified by the upper air passages, giving it a low-pitched, grunting sound. I could get no sound at the epigastrium and there was no apparent effort of the diaphragm or abdominal walls as if expelling flatus from the stomach. The sound continued while she was talking and breathing. It did not appear to be a moan or grunt or like a regurgitation of air from the stomach.

I gave her some potassium bromid, tincture of nux vomica, and compound tincture of cardamon and mint water. She called next day and I found that the heart had quieted down and that the gushing sound was absent. She said that after the first dose of medicine the heart quieted down and the sound promptly disappeared.

A second case was that of a man about sixty-two years old, with dilated left and right ventricles. The sounds heard were similar to those heard in the case first reported and could be easily distinguished across a room. The sound had all the characteristics given in Case I. A short time later the patient died suddenly. No post-mortem examination was held.

Dr. J. Chalmers Fulton of Philadelphia told me that he had a case which I firmly believe to have been like the two cases that I have just reported of the loud, esophageal sound. I was to have seen this patient with the doctor, but he was absent from home the day we called. A short time afterward he was taken sick and died. The history is as follows: He was an old soldier. For years he had a continuous, grunting, nasal sound, synchronous with the heart's action. The sound was audible a great distance from the body. Dr. Fulton said that on a still day he had heard it across the street. It was much more audible when the mouth was open, and after taking a drink, or when excited. In fact, anything that increased the action of the heart seemed to increase the sound.

I examined the heart, which Dr. Fulton removed after death, and found nothing, except that it was generally hypertrophied. Two skilled pathologists examined it and informed me that there was nothing in the arrangement or construction of the papillary muscles, tendons, valves, or any other part of the heart to account for any abnormal sounds. From the history and the post-mortem returns I feel satisfied that this case was one similar to the two before reported.

In this class of cases the sound was diagnosticated in two instances as being of endocardial origin. It is true that the subjects all had organic heart disease, causing enlargement of the organ, but the sound heard so plainly was evidently exocardial. The sound seemed to be from the esophagus or, at any rate, from the fauces. I cannot understand how the heart could be powerful enough to force air out of the lungs with sufficient rapidity to cause so loud a sound especially during inspiration. It has occurred to me that in some of the individuals reported as having had extraordinary loud murmurs during life, without pathological changes being found after death, the case might have been of the kind here reported. Two were so considered by the medical attendants.

The sound always suggested the expulsion of a small quantity of air. My reasons for believing that it is an esophageal sound are: First, it seemed to come from the fauces; second, closing the mouth muffled the sound; third, on auscultation it was heard down to the middle of the sternum, and not

[1] Read at the sixteenth annual meeting of the American Climatological Association, held at New York, May 9, 10, and 11, 1899.

below that point. The only explanation that occurs to me which seems at all plausible is that the heart in diastole pressed out of the esophagus a small amount of air, which was re-admitted during the contraction or systole of the organ. At one time I thought it might be that the contraction of the heart opened the gullet so as to allow the escape of flatus from the stomach, but this thought was dispelled when I considered that the stomach could not possibly furnish gas enough to continue the sound for days or, as in one case, for years.

Esophageal Clicking. — This is a short, sharp, clicking sound heard generally at the end of expiration. It is plainly audible as coming from the fauces and is quite evanescent, being clearly distinguishable to-day and gone to-morrow. It is absent before a meal and present during digestion. This sound has all the peculiarities of modification of the louder, gushing sound, being dulled by closing the mouth. I have noticed this clicking in several cases.

One case in my own family I have studied very carefully and for a number of years. When the subject was twenty-five years of age this clicking sound was often noticed with the action of the heart toward the end of expiration, when one, two, or three small, sharp clicks were heard, stopping as soon as the next inspiration began. This sound was often noticed after a full meal, drinking of stimulants, active exercise, and especially after riding rapidly on the back of a rough-trotting horse. It was sometimes noticed after lying down at night without any assignable cause. The sound was subdued by closing the mouth and generally stopped by curtailing the respiration. A forced, held expiration increased the number of clicks. In this case there was no evidence of hypertrophy of the heart or any endocardial disease.

To my personal knowledge the patient had this sign more or less for thirty-eight years, it being absent for years at a time. This is one of three or four cases that I have seen. In all the cases the clicks were interrupted by inspiration.

This sound is so slight that it might be present and not be noticed by the physician or the patient. Therefore, I suppose that it is more common than the louder sound, as I have never had a patient sent to me in whom it was previously detected by a physician. My explanation of this click is that it is caused by the separation of two moist surfaces. That the heart causes it is proven by the fact that it keeps time with the heart's action. I find in the case reported that it occurred about the time of the systole of that organ. In this connection it may be of interest to state that Dr. J. J. Walsh of New York has called my attention to the fact that Bernhardt of Berlin has reported cases of clonic contraction of muscles, giving a sound or click in the ear, attributed to this clonic contraction of muscles in the neighborhood of the Eustachian tubes. These sounds could be heard at a distance from the ear and occurred as often as 80 to 120 times a minute without reference to the heart's action.

There is another faucial clicking sound which is quite common. It occurs with each round of respiration and is frequently found in subjects with old pulmonary cavities especially near the apices. This click also comes from the fauces but can be easily differentiated from the click here described by observing that it occurs with each respiration and is not synchronous with the heart-beat. I am inclined to think that these two unusual sounds that I have described are produced by the action of the heart on the esophagus; so I have presented them together in this paper.

Let us look at the anatomy of the parts: The esophagus, as found in the post-mortem room, is contracted and flattened. The walls are flaccid, having no elasticity. The position of the esophagus is found to be directly behind the heart with a small intervening space between it and the left auricle and left ventricle. They are so close that the heart has been wounded by foreign bodies which first became lodged in the esophagus. The aorta is at the side and not far away. Anatomists inform us that Trutz has found between the pericardium and the anterior surface of the esophagus a muscular slip or band. It occurred to me that if this muscular slip were abnormally developed it might influence the esophagus provided the pericardium were adherent. The study of the anatomy of the parts does not throw much light on the subject under consideration. If the esophagus were an elastic tube the explanation would seem to be easy. A mediastinal tumor, with a rigid esophagus, might introduce conditions that would assist us in our explanation of the loud sound which we are considering. You will remember that in all the three cases in which the sound was heard the heart was enlarged.

Recapitulation. — 1. The sounds were heard at the beginning of the systole of the heart and, in two cases, diagnosticated as an endocardial murmur.

2. The sounds of both were modified by respiration, being heard most markedly at the end of expiration.

3. They were all more or less evanescent, except in the case of the old soldier.

4. They were increased or developed by a full stomach, stimulants or excitement.

5. The sounds were increased by opening the mouth, and dulled by closing it.

6. They were heard by auscultation at the middle of the sternum, but very much subdued as compared with the sound heard at the open mouth.

7. The sound was not transmitted in any direction from mid-sternum.

8. They were not heard by auscultation over the stomach.

THE HYDRIATIC TREATMENT OF PNEUMONIA.[1]

BY RICHARD K. MACALESTER, M.D.,
OF GLENWOOD SPRINGS, COL.

IN the limited time allotted to me for the discussion of hydrotherapy in pneumonia I shall endeavor to cover as much ground as possible by presenting in the form of a brief *résumé* the well established data of this rather extensive subject. Those wishing to familiarize themselves with details will find this branch of therapeutics elaborately treated in a recently published book by Dr. S. Baruch of New York,[2] to whom indeed, as to Winternitz in Europe, great credit is due for the development and propagation of hydrotherapeutics in this country. I was fortunate enough to have had instruction from both the aforenamed authorities, from which, as well as from their writings, I shall quote freely without special reference in this paper.

Many observers of the widest experience in the treatment of pneumonia by various methods extol the virtues of hydrotherapy, and comparative statistics demonstate its therapeutic efficiency. Thus for instance, Fenwick of the London Hospital in an analysis of 1000 cases of pneumonia met with failure in but 10 per cent. of those treated by various cold applications, whereas the mortality was double as great when other methods were employed. In J. Hood Wright Memorial Hospital, New York, the total mortality from pneumonia has been reduced more than one-half since hydriatic treatment has been adopted. Penzoldt, from the experience of an enormous material of 2200 cases of pneumonia in children, concludes that preference should always be given to a cautious bath treatment.

By first considering some of the physiological effects of cold applications to the body surface we can best judge as to their applicability and to what extent they meet the therapeutic indications in pneumonia. A moderately cold application to the skin causes a primary contraction of the cutaneous vessels which is followed by a tonic, active, dilatation in contrast to the passive hyperemia produced by warm procedures (as for instance, poultices). The latter relax the vasoconstrictors giving rise to a stasis, whereas cold stimulates the vasodilators, producing an active hyperemia, with maintenance of vascular tone and improved circulation. Mild, cold procedures, such as usually employed in pneumonia, act reflectively through stimulation of the cutaneous nerves, on the centers in the central nerve system, and thence upon the functional activity of various organs. The respiratory system is stimulated and inspiration deepened The effect on the circulatory system is stimulation of the heart action (evinced by more forcible ventricular contractions), and neurovascular excitation, in consequence of which arterial tension is raised and the blood propelled with greater velocity and force. The general condition is invigorated and refreshed and cerebral activity stimulated. The secretory organs evince greater activity, the amount of secreted urine, for instance, increasing considerably. Owing to the compensatory powers of the body, internal temperature is not materially influenced in health

By applying the foregoing data, it will be seen that the therapeutic requirements in pneumonia are well fulfiled, and that hydriatic treatment is based on a sound *rationale*.

The therapeutic indications are: (1) To stimulate and invigorate the nerve-centers with a view to enhancing the patient's vital powers; (2) to prevent and control heart failure: (3) to reduce temperature; (4) to eliminate toxins (Baruch).

1. The stimulating action of cold applications on the nerve-centers is reflected to organs of vital importance, upon whose functions the patient's resisting powers to the toxic substances, generated by the the diplococcus pneumoniæ Fraenkel, are dependent. Soon after applying cold the patient grows calmer, respiration deeper and more regular, dyspnea is relieved, and expectoration facilitated. There is also improvement of appetite and sleep, and in the functions of the skin and kidneys.

2. Heart failure, the most dreaded complication in pneumonia, is better averted by hydriatic measures than by any other available means. The heart action is aided and maintained in the following manner: The active hyperemia of the skin, following the rapid, primary contraction of the cutaneous vessels, relieves the heart at once by broadening the stream in the cutaneous capillaries. At the same time arterial tension is raised, as proved by the better filling of the radical arteries, and a freer, unembarrassed pulmonic and systemic circulation is established. When we consider the enormous vascular area of the skin, estimated as being capable of hold-

[1] Read at the annual meeting of the Colorado State Medical Society, held at Denver, June 20–22, 1899.

[2] S. Baruch, "Hydrotherapy," Wm. Wood & Co., New York, 1898. See also "Hydrotherapy in the Pneumonia of Children," MEDICAL NEWS, November 19, 1898, and Winternitz, "Die Hydrotherapie auf Physiol. und Klin. Grundlage," Vienna and Leipsig, 1899.

ing 30 to 50 per cent. of the entire blood of the body, we can readily realize that this is a mighty source of depletion.

3. The fact that pneumonia patients are extremely susceptible, and that their temperature may be easily reduced by cold procedures, necessitates great care and precaution in the application of such measures. Although high temperature may be an important element in pneumonia and other infectious diseases by imposing more work on the heart, and adding greatly to the patient's discomfort, still it is by no means the chief danger. As I have often insisted, in discussing the matter, fever is but a symptom of disease, indicating the reaction on the part of the organism in its struggle to overcome the infection process. If vitality sinks so low as to offer no resistance to the toxemia, there is no fever, and the patient collapses at once, an occurrence which we have all had occasion to observe in lethal cases of pneumonia. Therefore, the indiscriminate administration of antipyretics with a view of reducing temperature, and thereby meeting the principal therapeutic indication, is as fallacious as is the idea, so deeply rooted in the professional mind, that the main attribute of hydrotherapy in febrile diseases is reduction of temperature.

4. The support that cold applications give to the nervous system, raising the patient's vitality and the functional activity of various organs, is conducive to the elimination of toxins.

The Hydriatic Method in Pneumonia.—Owing to the susceptibility of pneumonia patients to cold, the milder hydriatric procedures, such as the cold chest-compress or the wet pack, are indicated n general. Furthermore, these are more easily applied and controlled, and are attended by less agitation, disturbance and exertion on the patient's part. In the experience of others, as well as in my own, the milder measures are indeed quite adequate to fulfil all the therapeutic requirements in both the croup ous and catarrhal pneumonia of adults. The cold chest-compress is preferable to other procedures in pneumonia, a conclusion I had reached independently some time ago, and which I now find is in harmony with the opinion of some others. Its correct application, as of all hydriatic procedures, requires some experience and care, therapeutic failures being usually due to faulty technic. The chest-compress is composed of three folds of linen or old muslin cut in a manner to fit the entire chest, from above the clavicles down to the umbilicus, with slits in the axillary regions to form flaps and cover the shoulders. It is then wrung out of water, so that it does not drip, at a temperature of 60° F., snugly applied around the thorax, covered with a piece of closely woven, thin flannel of the same shape but at least an inch wider in all directions, and secured by safety-pins. At first the compress is changed every half hour, then every hour or two, until the patient's temperature is below 100°, when it may be discontinued. The compress should not be covered with oiled silk, a very popular proceeding on the part of attendants for the sake of convenience and protection of the patient's bed and clothing, as this would convert it into a poultice and deprive it of its stimulating and gradually cooling action.

The wet pack, at a temperature of 60° to 70° F., being a somewhat more severe procedure than the chest-compress, is indicated in the graver forms of pneumonia with high temperature. It is a very popular and efficacious method, has warm advocates, and deserves special mention.[1]

Other hydriatic methods in pneumonia advocated by prominent observers are cold full-baths (temperature 60° to 70° F.), tepid baths (90° to 92.5° F.) both with or without friction and ablutions, ice packs, the ice-cradle, cold sponging, etc.

In the pneumonia of children, the same methods as just enumerated for adults are employed in somewhat modified form. The child's sensitive nervous organization, with its greater susceptibility to cold and the development of nervous symptoms, and the minor resisting powers of the heart, as compared with the adults', render sound judgment in prescribing and extreme care in the application of hydriatic procedures imperative.

In my experience, based on the observation of a considerable number of patients treated during my practice in New York, the cold chest-compress alone proved a reliable and adequate remedy in the vast majority of cases. For children under three years of age Baruch favors tub-baths of 5 to 8 minutes' duration, with continuous friction, at a temperature of 95° F., gradually reduced to 85° or 80° F., according to the body temperature, whereas in older ones preference is given to the cold chest-compress. He also recommends the copious administration of cold water at regular intervals in the pneumonia of both children and adults, and I need scarcely add that a hygienic régime should be strenuously adhered to.

Epicrisis. — The virtues of hydrotherapeutics, being based on sound principles and scientific clinical evidence, entitle them as much to adoption by the profession at large as do the popular medicinal remedies in routine practice. I do not presume to say that drugs can be dispensed with; they have their place and field of usefulness; but their pro-

[1] While I was attending Professor Winternitz' clinic in Vienna this method was employed extensively in pneumonia with excellent results.

longed administration is often depressing, nauseating, or toxic, to the one or other organ, and they do not always fulfil the requirements of judicious treatment. In support of this view and in connection with the pneumonia of children allow me to detail an illustrative case from my past experience:

H. R., a well-developed girl, three and a half years old, was taken ill after measles with pneumonia five days previous to my first visit. I saw at a glance that her condition was very serious, and on examination found the entire and middle lobe of the right lung consolidated. Her temperature was 103.2° F., her pulse scarcely appreciable, approximately 160 per minute, her breathing rapid, superficial and obstructed, her lips and extremities markedly blue from cyanosis, and she was failing fast. On inquiry I ascertained that she had been given various kinds of medicines, all of which were inefficacious, had vomited during the previous two days, and it was with difficulty that any nourishment could be retained. I demonstrated to the parents how to use the cold chest-compress by applying the first one myself and prescribed a simple expectorant. In about an hour improvement began; the cyanosis disappeared, the pulse became stronger and slower, the respiration deepened, and, in short, the child was actually resuscitated. Shortly afterward she fell into a peaceful sleep. From then on she progressed uninterruptedly, and was convalescent two days later.

In conclusion, I ventured to state that anybody who has witnessed a few such transformation scenes as the one just described, resulting from the correct application of water after medicinal agents have proved futile, will become a convert to hydrotherapy.

A NEW METHOD OF TREATING COMPLETE TEAR OF THE RECTOVAGINAL SEPTUM BY TURNING DOWN AN APRON INTO THE RECTUM AND BY BURIED SUTURE THROUGH THE SPHINCTER MUSCLE.[1]

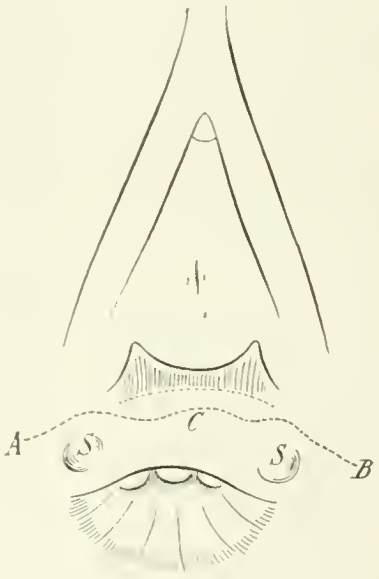
By HOWARD A. KELLY, M.D.,
OF BALTIMORE, MD.;
PROFESSOR OF GYNECOLOGY IN THE JOHNS HOPKINS UNIVERSITY.

IN a paper published in the first number of the *Johns Hopkins Hospital Bulletin* of the current year I endeavored to impress upon the profession the importance of treating complete tear of the rectovaginal septum by dissecting out and liberating the buried sphincter ends, and then by uniting the freed ends by two or three interruptured catgut sutures buried with the muscle in the septum. I also showed the entire practicability in these cases of passing a splinting silkworm-gut suture directly through the center of the muscle, so as to take the tension off the buried catgut sutures, instead of passing the splinting suture well behind the muscle as in the Emmet operation.

Since the presentation of that paper with report as of series of cases which were destined to show that the immediate results of the new method were different from and remarkably better than those obtained under any previous plan, I have devised the following procedure as an additional and final step in the treatment of these cases.

The plan of turning down the flap toward the bowel did not originate with the writer. I am indebted to the courtesy of Dr. James R. Chadwick of Boston, who has called my attention to the fact that a procedure identical in all important particulars has been described by Dr. James Collins Warren of Boston in the *Boston Medical and Surgical Journal* of January 3, 1878, and in the *Transactions of the American Gynecological Society*, vol. vii, 1882. It only adds to the value of the method

FIG. 1.



to know that the credit of the invention belongs to our distinguished fellow-countryman, Dr. Warren, and I am glad to learn that instead of being new it has already stood the test of trial at his hands.

Dr. Warren's description in every important particular covers the points I would make, leaving as original in my procedure two things: First, the combination of a flap turned down into the rectum with the buried suture to the dissected sphincter; and, second, the use of figure-of-eight sutures buried in the septum to do away with the dead central space.

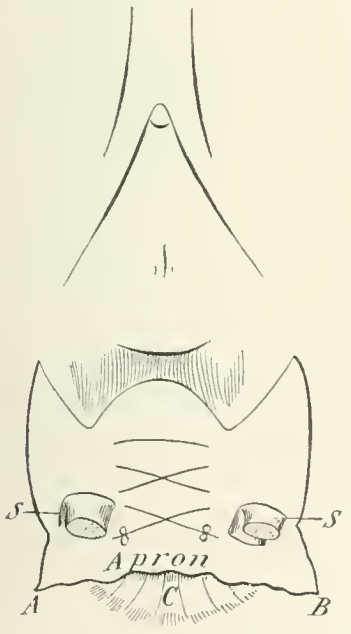
The method for performing the operation is as follows: The area to be denuded is outlined by making the basal incision across the septum on the vaginal side in advance of the sphincter ends, and at least 1 cm. in advance of the margin of the rectal mucosa. The denudation then extends up into both vaginal sulci in the usual manner. The important point in which the operation differs from the ordinary Emmet procedure, generally employed, lies in the treatment of the undenuded portion between the

[1] Abstract of a paper read at the Twenty-fourth Annual Meeting of the American Gynecological Society, at Philadelphia, May 23, 24, and 25, 1899.

basal line and the rectum. Instead of cutting this off in strips, it is dissected loose from above downward and turned down toward the rectum like an apron. The purpose of this fold or apron is to protect the broad wounded surface in the septum from any contamination on the side of the bowel, which it does in the following manner: As soon as the stitches are passed which bring the septum together from side to side, the apron of tissue is also folded loosely together and turned down toward and sometimes projecting entirely from the anal orifice. This at once protects the septum from infection, as every movement of the bowels only tends to push this curtain down and out, and no longer tends to force fecal matter up between the stitches. This natural tendency of the apron to protect the septum is reinforced by a series of delicate sutures uniting the edges. I have sometimes even left these sutures long and fastened them outside so as to hold the margins of the wound out on the surface of the body, in this way entirely doing away with any wound on the rectal surface, and robbing the operation of its only serious complication.

I next proceed to make a separate dissection of the sphincter ends by setting them free in the manner described, and when this is done the suturing is begun by drawing together the internal sphincter, which is well exposed, by a series of figure-of-eight sutures extending well up into the septum and obliterating entirely the

FIG. 2.

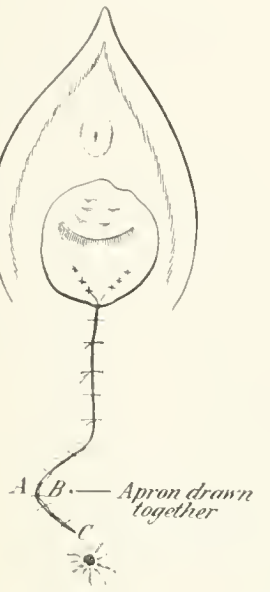


dangerous dead central space. Three or four of these figure-of-eight sutures applied in this way take the place of three times the number of interrupted sutures as formerly applied on the side of the rectum.

After closing the central portion of the septum by the figure-of-eight sutures, the sphincter ends are united by three interrupted catgut sutures. I next apply the sutures to the sulci, then to the perineal surface, using one or two silkworm-gut sutures for splinting purposes. Then, finally, I unite the edges of the apron seen projecting from the anal orifice by some very fine silk or catgut sutures.

The advantages of this operation are, first, that it secures immediate good sphincter control, and, second, that it removes from the operation the complication occasioned by the wound on the rectal surface.

FIG. 3.



MEDICAL PROGRESS.

The Eruption of Typhoid Fever —BROWNSON (*Charlotte Med. Jour.*, July, 1899) discusses the question of spots in typhoid fever. Inquiry of his medical associates revealed the fact that most physicians practising in the mountainous part of North Carolina regarded the eruption in typhoid as a rare exception. Painstaking examination in a large number of patients convinced him, however, that this opinion was an error and that typical spots are present in at least fifty per cent. of the cases. He rejects the idea that the presence of these spots in typhoid indicates that the patient has suffered or is suffering from malarial infection.

Outbreak of Secondary Carcinomatous Nodules, Thirty Years after Operation.—HEURTAUX (*Arch. Prov. de Chir.*, No. 2, 1899) cites an illustration of the very long interval which may exist between an operation for cancer and the development of secondary nodules. The patient in question was a woman whose breast and axillary contents had been removed on account of carcinoma thirty years ago. After that long period of immunity there appeared in the scar and its neighborhood, in the axilla, and finally in the thorax and vertebræ, multiple nodules of carcinoma, which grew with great rapidity. Heurtaux was satisfied that they did not represent a new carcinoma, but that they developed from the seeds of the former tumor, which had lain dormant all those years.

Resection of a Part of the Vena Cava for Carcinoma.—MANTEUFFEL (*Centralbl. f. Chir.*, July 8, 1899) removed the carcinomatous right kidney of a man aged forty-nine years. The vessels were ligated in two places and divided. The kidney remained attached to the vertebral column by its lower pole. A careful examination showed that the carcinoma had grown from the lower end of the kidney through the wall of the vena cava, and that masses were floating like sea-weed in the venous stream. The kidney was removed, the vein compressed above with an artery clamp whose jaws were covered with rubber tubing, and while assistants held the vein below, the affected portion of the wall was removed. The opening so made was 9 cm. (3.6 in.) long, and 2.5 cm. (1 in.) wide. Blood from the left renal vein spurted freely from this opening, but it was held in check by compression until two rows of stitches had been put in place. There was still a little leakage, but this ceased as soon as the artery clamp was removed and the normal venous flow was resumed. The compression of the cava had lasted fifteen minutes, during which time the pulse was scarcely perceptible. In two minutes after the removal of the clamp it was full and strong. The patient suffered somewhat from collapse in the first twelve hours, but made a quick recovery, and was out of bed in eighteen days. There were never any symptoms which indicated circulatory disturbance of any character.

The Right-Angle Continuous Intestinal Suture.—CUSHING (*Boston Med. and Surg. Jour.*, July 20, 1899) uses fine white silk, machine twisted, J. D. Cutter No. 000, for intestinal suture. The needle is inserted at about one-eight of an inch from the cut edge and emerges parallel to the cut edge at the same distance from it. It is withdrawn and a similar stitch taken in the other cut edge of the bowel. This procedure is repeated until the whole circumference of the bowel has been sutured. Tests have shown that this continuous Lembert suture, as it is sometimes called, affords an exact approximation capable of withstanding pressure from within sufficient to rupture the gut. The mesentery is united by interrupted sutures. The silk is sterilized by boiling and preserved in ninety-five per cent. alcohol containing one-tenth per cent. of corrosive sublimate. The best needle is a self-threading or spring-eye, round sewing needle, $1\frac{1}{16}$ of an inch long, the point of which has been ground flat like the Hagedorn needle.

Treatment of Purulent Rhinitis in Children.—WALSHAM, in "Nasal Obstruction," says that the general health should be improved by the appropriate treatment of any digestive disturbance which may be present, and by the administration of cod-liver oil and the syrup of the iodid of iron—the last-named drug being of the greatest utility. If the oil is not well borne, small doses of Maltine may be used as a substitute, or the syrup of the iodid of iron be used alone. The local treatment should comprise the use of cleansing agents, Dobell's solution, or weak antiseptic sprays, solutions of boric acid, bichlorid of mercury or listerine, to be used every four hours, and the mucous membrane subsequently astringed by the use of sulphocarbolate of zinc, or a spray of menthol and eucalyptol (10 per cent.) in paroleine or olive oil, or by dusting with iodoform, iodol or boric acid. If the discharge, which may persist for a long time, does not yield to this plan of treatment, the existence of some condition such as the presence of a foreign body, should be suspected, and will probably be revealed by careful and thorough investigation.

Massage for Uncontrollable Vomiting of Pregnancy.—GEOFFROY (*Centralbl. f. Gyn.*, July 8, 1899) says that the uncontrollable vomiting of pregnancy is caused by reflex contraction of the intestinal tract. This action is localized in various parts of the small intestine, but especially in the ileopelvic angle of the colon. Painful contractions at this point are pathognomonic of reflex hyperesthesia of the alimentary canal, the symptoms of which are either cardiac pain, or temporary or continuous vomiting. Light massage judiciously applied to the colonic flexure will relieve these symptoms, according to the experience of the author in several cases.

Incontinence Cured by Gradual Vesical Distention.—HAVEN (*Bost. Med. and Surg. Jour.*, June 15, 1899) mentions two cases of incontinence in older girls which he succeeded in curing completely by gradual distention of the viscus with a four-per-cent. boracic-acid solution. Both patients were eighteen years old, and both from earliest infancy had wet the bed nightly, and had found it impossible to retain the urine for more than a few minutes while awake. The bladder of one held eight ounces under pressure, that of the other only three and one-half ounces. The treatment consisted in distending the bladder until discomfort was produced, after which the patient held the fluid as long as possible—ten or fifteen minutes in the beginning, though this time was doubled later. Distention was practised every other day, and improvement was rapid. Treatment was continued until the bladder would hold twenty ounces, and then all symptoms having been relieved, it was discontinued. The elapsed time in one case was three months and in the other five months. There was no evidence of abnormality in either case, other than that the bladder was small.

CONVULSIONS IN CHILDREN.

WHEN a period of intensely hot weather occurs late in the season and severe intestinal diseases develop in children as a consequence, it has been noted that their ailments are more frequently complicated by convulsions than under similar circumstances earlier in the summer. The wear and tear of life during the difficult heated months has apparently augmented the almost normal instability of the infantile nervous system, and as a consequence convulsive explosions of nerve force are to be expected. An interesting discussion of convulsions in children at the recent meeting of the British Medical Association brings out the present English views as to the etiology and treatment of the affection, and it seems a timely topic for the attention of all general practitioners.

Drs. Gossage and Coutts, to whom the subject was referred for special consideration and introduction to the Section, suggested in their conclusions the following points for discussion: First, the frequency of convulsions in children has been vastly overrated; second, the immediate danger from a fit has been overrated, while the danger as regards future neurotic manifestations has been underestimated; third, the predisposing causes are of much more importance than the exciting causes; the slighter exciting causes will not produce convulsions except in predisposed children.

There was very little disagreement with these propositions. The overestimation of the danger of convulsions, it was pointed out, came from the fact that in the terminal stages of many diseases of infancy convulsive movements occur, and that the death was then, unwarrantably, of course, set down to convulsions. As to predisposition, nervous heredity, etc., statistics were quoted to show that in over one-half of the cases in which patients reached adult life after having had convulsions in childhood they suffered from some variety of neuroses. These were not due so much to the malnutrition of the nervous system during infancy or to damage during the convulsive stage as to congenital faulty development. It is particularly the children of nervous, gouty, rheumatic, or diabetic parents that are liable to fits, and it is in patients in whom such a family diathesis is known to exist that any extreme of reflex irritation must be repressed or it will result in a nervous explosion.

As to treatment the discussion did not bring out anything striking, except, perhaps, by negation of the necessity for active measures. The referents said:

> All that is necessary during an actual attack of convulsions in most cases is to loosen the clothing about the neck, chest, and abdomen, and lay the child on its back with the head slightly raised until it recovers from the fit and the subsequent drowsiness. The placing of the child in a hot bath, as is such a common practice, probably does no harm, and if the child be in feeble health it may be advantageous to use a mustard bath, which has decided stimulating properties.

Very few American physicians would be content to be as inactive as our English friends suggest with anxious parents and relatives about. For the very severe convulsions or prolonged unconsciousness after a fit inhalations of chloroform even to deep narcosis were suggested. Small doses of the bromids were recommended for some days after the attack. The recurrence of an attack suggested the continuance of the bromids for weeks at least,

any harm that may be supposed to attend their use being more than counterbalanced by their benefit if they prevented the return of the convulsions.

METHYLENE BLUE AS A SEDATIVE IN INSANITY.

The history of the use of methylene blue in general therapeutics is similar in many respects to that of other aniline compounds. Early reports, backed by commercial interests, were indicative of its value as a general panacea for many of the ills of the flesh, but of recent years it has found an established though restricted field in a limited number of affections. Its value in malaria admits of little doubt and in migraine and other nervous affections evidence is slowly accumulating that will give it a recognized position among the hypnotics.

Recent studies by P. Bodoni of the University of Genoa (*Klinisch-therapeutische Wochenschrift*, No. 21, 1899, p. 666) seem to show its wide applicability as a sedative in excited mental states. He reports some fourteen cases in which the remedy was tried: these included such conditions as simple acute mania, mania with furor, periodic mania, chronic mania, and the mania of chronic alcoholism, periodic melancholia, paranoia with delirium, hystero-epilepsy, and puerperal mania. In all of these cases the remedy was administered by hypodermic injection into the gluteal muscles, in amounts varying from one to one and one-half grains. Its sedative action became manifest within from three to six hours and usually persisted a day or, in some of the cases, even for three to four days. The quieting action was not attended by any narcotic effect and there were no unpleasant after symptoms observed.

The cause for its action is not definitely understood. By analogy, bearing in mind the use of this substance in technical microscopy by reason of its affinity for nerve tissue (methods of Ehrlich, Nissl, etc.), it would appear that it has a specific action on these tissues during life. This, however, has been denied by some observers who are inclined to class the drug with the blood poisons, acetanilid, etc., and thus explain its pharmacological action. The author believes that it should take its place with others of the hypnotics, such as chloral, amylenhydrate, trional, and even hyoscyamus.

LEGAL CONTROL AND TREATMENT OF INEBRIATES.

The Legislature of the Australian Province of New South Wales has passed a law the practical workings of which will be followed with great attention by all who are interested in the various questions involved in the management of inebriety. According to the provisions of this law habitual drunkards are made amenable to State control and may be legally committed for treatment to certain institutions for definite periods of time. For the purposes of the law "Inebriate" means a person who habitually uses alcoholic liquors or intoxicating or narcotic drugs to excess: "Institution" means a place licensed under this Act or established by the Government for the reception, control, and treatment of inebriates.

The commitment is executed by a magistrate only after application in due form and after the submission of a physician's certificate, together with corroborative evidence by some other person or persons, that the person named is an inebriate and after the appearance before the judicial authority of the individual claimed to be the inebriate. It is within the discretion of the committing authority to send the prisoner for twenty-eight days to some private or public hospital or to his own or a friend's house there to be under control and treatment, or to commit him to a licensed institution for a period not more than twelve months. The law contains besides some very practical provisions to prevent its being abused or employed for purposes other than that intended—the good of the inebriate.

The Australian legislators seem to have devised a valuable measure for the solution of the trying problems associated with inebriety. Their treatment of the whole question of the habitual abuse of alcohol and drugs as a pathological condition that practically makes its victim irresponsible and therefore amenable to State control and discipline is thoroughly in accordance with modern medical views in the matter. Too much regard has previously been paid to the liberty of the individual. We congratulate our Australasian brethren of the medical profession, (for it is to their labors the law is due) on the success of their efforts to have the legal status of inebriety placed on a common-sense basis. We shall watch with interest the workings of the law

and hope to hear of further legislation along the same line among other English-speaking peoples.

THE STANDARDIZATION OF DRUGS.

An important work has been appointed to be done in Washington next May when the Revision Committee representing the American Medical Association, the American Pharmaceutical Association, and other bodies interested in therapeutics will meet for the purpose of conducting the customary decennial revision of the American pharmacopœia. Questions of unusual importance will come up for consideration and decision, and there is ground for no little satisfaction in the fact that the delegates appointed to represent the American Medical Association—Dr. Hobart A. Hare and Dr. George M. Gould of Philadelphia, Dr. F. E. Stewart and Dr. R. G. Eccles of New York, and Dr. Warren B. Hill of Milwaukee, Wis.—are men who, besides being well qualified to adjudicate on the points at issue, possess in a peculiar degree the confidence of the entire medical profession, and also of those engaged in the manufacture and sale of drugs. If the other constituent bodies are anything like as well represented, the Revision Committee will be one to which it will be possible to look with confidence for such a discharge of its duties as will make the meeting of 1900 an epoch-making stage in the history of the standardization of drugs.

Hitherto the practice has been to fix a standard of strength only for such drugs as are amenable to chemical assay. This includes, of course, such drugs as nux vomica, opium, and cinchona, regarding which standards were formally adopted at the revision conducted in 1890, and also ipecac and belladonna which the British pharmaceutical authorities have since added to the pharmacopœia recognized in the British Isles. The American revisers will no doubt include the latter drugs in the new pharmacopœia of this country, and it is highly probable that they will likewise admit and fix standards for the Calabar bean, gelsemium, hyoscyamus, podophyllum, colchicum, conium, stramonium, and veratrum, all of which lend themselves to chemical analysis.

The question is whether the work of the committee should stop here. Why, it is asked, should no standards be fixed for such drugs as ergot, digitalis, strophanthus, aconite, and cannabis indica? They are all drugs which are in universal use, and their quantitative standard is surely of as much consequence both to the physician who prescribes the remedy and to the patient who takes it as that of any other medicine. "It matters little," as one authority observes, "how much crude ergot goes to the fluid pound of the extract if the fluid fails to produce a characteristic physiologic action." What then is the objection to standardizing these drugs as well as others? Only this, that the drugs in question are not amenable to chemical assay, or at all events cannot in the present state of chemical knowledge be assayed chemically with a sufficient degree of accuracy to justify the fixing of a standard, measured quantitatively. But is this any reason why no attempt should be made to fix a standard by other means? Scientific inquirers conducting private investigations are not content to rest there, and neither are the higher class of manufacturing chemists. Acknowledging and making use of the chemical test whenever it can be applied with satisfactory results, they have recourse to physiologic tests, which as regards the question of potency are for all practical purposes equally reliable. At present, as has been pointed out, a practitioner who writes a prescription, say for digitalis, in a dozen different parts of the same town will find in some instances that he obtains a drug which exhibits a satisfactory physiologic action, and in others no satisfactory action whatever. This is submitting the drug to a physiologic test when it is too late. If, instead of leaving the patient to be experimented on, similar tests had previously been made with the article on some of the lower animals, the potency of the drug would have been known, and the doctor would be aware of the exact strength as well as the nature of the remedy he was prescribing. That the present condition of matters in this respect is recognized by the profession as eminently unsatisfactory was shown by the discussion which took place at the recent meeting of the American Medical Association at Columbus, Ohio, and it is hoped that the Revision Committee will deal with the subject in a sufficiently bold manner to provide an adequate remedy. To this end, however, it is necessary that it should be fortified by expressions of opinion both

from medical men and the manufacturers of drugs, it being to the interest of none, so far as we can see, except traders in inferior classes of drugs, to oppose the standardization of as many as possible of the drugs that are used in the practice of therapeutics.

ECHOES AND NEWS.

The Health of the Prince of Wales.—The Prince, during his recent visit to Marienbad was very democratic. While sitting on a park bench, a Polish Jew, not knowing his identity, began to question him about what he paid his doctors, etc. Finally he digged His Royal Highness in the ribs and told him he looked too healthy to need the water cure.

Cuban Yellow-Fever Statistics for August —According to the official returns for yellow fever in Cuba up to the end of August, there were, all told, 55 cases and 20 deaths during the month. The cases were distributed among natives and Americans as follows: Cubans, 39 cases, 9 deaths; Americans, 16 cases, 11 deaths. It is especially at this season of the year that fatal cases develop among the unacclimated.

Arizona's Petrified Forest —Dr. Lester F. Ward, one of the two experts on fossils with the United States Geological Survey, has gone to Arizona to secure for the Commissioner-general of the Land Office an opinion on the advisability of setting aside the famous petrified forest in that State as a National Park. Dr. Ward is an honorary curator of the National Museum, and is connected with the Smithsonian Institute.

The Lane Medical Lectures.—Sir Michael Foster, K.C.B., the distinguished English physiologist and author, will deliver the Lane Medical Lectures for 1900 in San Francisco. The lecturers in preceding years have been Mr. Christopher Heath of London, the well-known surgeon; Professor Clifford Allbutt, whose system of medicine has been so favorably commended in recent years, and our own Dr. Nicholas Senn of Chicago.

Mosquito Plague in London.—A mosquito plague of unusual dimensions has attacked the northeast of London. Bandaged heads, bootless feet, and swollen hands are conspicuous everywhere. It seems that about three weeks before the appearance of this plague Mare street was repaved with jarrah wood; and it is believed that the eggs must have come from Australia with the wood, and that Mare street has been converted, with the aid of the tropical sun, into a mosquito incubator.

Autobiography of Orfila.—It is announced by his heirs that Dr. Orfila, who was Professor in the Paris Faculty of Medicine and Dean of the Medical School from 1830 to 1848, left behind him an autobiography. Orfila was, as will be remembered, a distinguished medico-legal expert and was concerned in most of the great cases involving expert evidence during the interesting years from 1845 to 1848. Since the autobiography must also contain a picture of medical life in Paris for the first half of the century, it is hoped that it will soon be given to the public.

Obituary. — Sir Edward Frankland, the well-known chemical expert on water-supplies, who has been prominently connected with London's water-supply for nearly forty years, died recently in his seventy-fifth year while on a vacation in Norway. He was the father of the well-known bacteriologist and expert in the bacteriology of water, Mr. Percy Frankland. Sir Edward was known for his discoveries of the compounds of zinc with methyl and ethyl, and for the theoretic considerations they suggested. For this he was elected Fellow of the Royal Society, and was for years its Foreign Secretary.

Hospitals in the Philippines. — In view of the increased army now being sent to the Philippines, Surgeon-general Sternberg has issued orders for an increase of the Medical Department and hospital accommodations at Manila. As six months is required for building a large wooden hospital, it will be necessary to depend either upon tent hospitals or upon buildings already constructed which may be obtained for the purpose, 500 hospital tents have been ordered. Two hundred and fifty members of the Hospital Corps will be sent on the "Missouri," and twenty female nurses on the "Relief." Four experienced Surgeons of Volunteers, with the rank of Major, are now under orders for Manila in addition to the commissioned medical officers belonging to the new Volunteer regiments.

England's Fear of the Plague.—Sir Joseph Ewart, president of the medical section of the Sanitary Congress which met at Southampton, England, on August 30th, predicted that the near advent of the plague would find out England's weak places. Professor Simpson urged the Government to begin precautions at once against invasion and to send a small commission of physicians and bacteriologists to Portugal to study the diseases on the spot. Another proposal was that the plague commission recently engaged in India should now crown its work by a study of the same disease under European conditions. Other English expert opinion is that as these plagues are spread by contaminated drinking-water or body parasites England's best precaution is not elaborate quarantine, but persistence in personal and municipal cleanliness.

Alcohol and Life Insurance — According to the *British Medical Journal* the mortality statistics of the Abstainers and General Insurance Co. of England make a very favorable showing for total-abstainers. The tables for the first fourteen years of the company's existence show that but forty-eight deaths occurred among total-abstainers for every 100 that might have been expected to occur according to the ordinary actuary statistics of deaths and the expectation of life in the general population. Abstainers are now claiming the right to lesser premium-rates than are accorded even to the moderate drinkers

of alcohol, for their death-rate seems to be notably less. It deserves mention, however, that this lessened mortality does not occur among abstainers who are reformed drunkards. Former indulgence in alcohol leaves its mark on their system and they do not enjoy the comparative immunity from disease accorded to life-long abstainers.

A Pneumatic Sole.—A recent air-containing appliance for the shoe is meant to be used in walking and bicycle shoes and the soles of boots in horseback-riding and the like. Experiments with rubber heels have shown that much irritation of the nervous system, especially in neurasthenic subjects may be prevented by avoiding the successive shocks of hard-heeled shoes. Tender feet are frequently a cause of insufficient exercise, so that this subject of improved footwear is of special interest to physicians. The invention was made by an Italian, Signor Fabro of Udine on the Austro-Italian frontier. It consists of a rubber tube bent in the shape of a staple, or letter U. This is placed between the inner and outer sole and extends from the heel to a little past the center of the foot, where the tube is cut so as to form a bevel. The tube acts as a spring, and air is supplied to it at the back of the heel and at the lower ends of the tube. The back of the tube is also slit to allow a free circulation of air. It has been found that such a shoe is very valuable for use on long walking tours.

The Yellow-Fever Situation.—As we go to press the excitement over the development of cases of yellow fever at Key West and New Orleans is subsiding. The type of the disease thus far in Key West has been very mild, the mortality being less than 10 per cent. Unacclimated persons who have not been exposed have been encouraged to leave for the North. The names of those who left the city, and who might prove sources of infection later because of exposure at Key West, have been secured and they will be kept under observation. The Marine Hospital Service and the Health authorities of Florida are acting in very harmonious concert and both promise that the epidemic will be kept well in hand. At New Orleans no new cases were developing at the beginning of the week and it seems as though the epidemic is over for the present at least. All alarm in the city itself is past and there has been very little disturbance of commerce. The neighboring Southern States, as a rule, did not even deem it necessary to quarantine against goods coming from New Orleans.

The Plague Situation in Europe.—The case of plague reported to have been discovered at a London hospital last week has proved on investigation to be a figment of the imagination of an enterprising reporter. At Oporto three new cases were reported last week but no deaths, and this week three cases with one death. The sanitary cordon between Spain and Portugal is about completed. The Spanish Government interdicted all intercourse between the two countries, until the five quarantine stations on the frontier were established. Three of these were in working order last week and the others are supposed to be ready by this time. The temper of the Portuguese people has changed very materially with regard to the disease. At first they scoffed at the idea of the existence of plague, then they refused to believe the assurances of sanitary experts and were riotous because of the enforcement of quarantine regulations. But the realization of the seriousness of the situation is gradually becoming widespread and the enforcement of the precautions necessary is accepted more willingly.

Diseases Less Dangerous to Life.—Dr. Samuel W. Abbott, Secretary of the Massachusetts Board of Health, has presented statistics to show that diseases are growing less dangerous to human life. The hygienic condition of the people in that State was better last year than at any previous time for a half a century. There were fewer deaths by 1263 from infectious diseases than during the previous year, though the population in the meantime increased from about 2,610,000 to about 2,665,000. The number of deaths from diphtheria decreased one-half, scarlet fever more than one-half, the deaths from consumption were about five per cent. fewer, and there were only about one-half as many deaths from measles as in the former year. The death-rate was reduced to eighteen per thousand, whereas it has been at nineteen for half a century. There was a slight increase in the number of deaths from certain diseases, including typhoid fewer, pertussis, and cholera infantum. The decrease in the death-rate is attributed to various causes, as improved sanitation, stricter quarantine regulations, and a better knowledge of disease.

Assistant Physician to the Government Hospital for the Insane.—The United States Civil Service Commission announces that on October 4, 1899, examination will be held at any city in the United States where the Commission has a board of examiners, for the position of assistant-physician, junior grade. The examination will be in letter writing, anatomy and physiology, chemistry, materia medica, and therapeutics, general and special pathology, surgery, bacteriology and hygiene, and obstetrics and gynecology. The minimum-age limitation for entrance to this examination is twenty years; the maximum none. The examination is open to both males and females. From the eligibles resulting from this examination certification will be made to fill two positions in the government hospital for the insane, one from the male register at $900 per annum and one from the female register at $600 per annum. Persons desiring to compete should at once apply to the United States Civil Service Commission, Washington, D. C., for application forms 304 and 375, which should be properly executed and promptly filed with the Commission.

Consumption of Quinin in the United States.—According to the official statistics of the Treasury Department over a billion and a half grains of quinin were imported by the United States during the year ending July 1st. This is equivalent to an annual consumption of something more than 20 grains by each inhabitant. The change that has occurred in the quinin industry in recent years is

well explained by the *Scientific American* in a recent issue. "As is well known, quinin, Peruvian bark, and calisaya bark are the products of the cinchona tree, which is a native of Western South America, more particularly of Peru and Ecuador. Now, however, but a small part of the supply comes from that region. At present two-thirds of the quinin consumed is produced in Java from cultivated trees. For many years the Dutch Government was urged to undertake the cultivation of this plant from Peru. Finally this was accomplished and a large number of specimens of the different varieties were obtained by botanists, who took them to Java in 1852. The English Government also started cinchona plantations in India which now produce large quantities of quinin."

MEDICAL MATTERS IN NEW YORK.

PORTUGUESE SHIP HELD—HOSPITAL ATTENDANTS INDICTED — VACCINATION COMPULSORY —ILLNESS OF DR. VON GRIMM—EMANUEL HOSPITAL PLANS—OBITUARY — BROOKLYN'S CHARITY BUDGET—FRAUDULENT LIFE RISKS—RABIES.

THE Portuguese steamer "Oevenum" arrived at this port on September 1st from Oporto, Lisbon, and St. Michaels. All on board were well. However, the "Oevenum" has been detained at quarantine for thorough disinfection.

Daniel O'Connor, Thomas Sexton, and Patrick J. Bryan, three hospital attendants in the Manhattan State Hospital, were charged on August 28th, with having caused the death of James McGuire, the paretic, who died on August 5th. It was claimed that the three attendants, in attempting to subdue McGuire during one of his violent spasms, threw him to the floor and beat him with a club. The charge of manslaughter was sustained.

President Murphy of the Board of Health is not satisfied with the manner in which the Brooklyn, Queens, and Richmond Borough School Boards enforce section 200 of the New York health laws relating to the vaccination of school children. They are requried to be properly vaccinated before being admitted to the schools. President Murphy threatens to prevent the opening of the schools until this rule is complied with.

Seven weeks ago Dr. Andrew von Grimm, an attending physician to the Babies' Ward at the Post-Graduate Hospital was bitten by a little patient while operating. His thumb was in the child's mouth, the gag slipped and its teeth inflicted what proved to be an infected wound. On August 31st Dr. John F. Erdmann operated upon the hand of Dr. von Grimm for the third time, amputating almost the whole of the affected thumb, and excising the epitrochlear glands. Recovery is now expected.

If the State Board of Charities shall approve the plans of incorporation of the Emanuel Hospital and Dispensary of New York, Dr. Maurice J. Burstein will select a site and erect a building thereon which he will present to the institution. Dr. Burstein's associates will be Drs. Ephraim K. Browd, Henry Levien, Maurice Caspe, Harris B. Addler, Abraham Hymanson, Israel Szlachecki, Max Wolper, Bernard Scheinkman, Joseph Barsky, Morris Cisin, Max Danidoff, George I. Miller, Max Landesmann and Max Moskievitz. These physicians will serve gratuitously and will act as the hospital staff. The establishment will be used principally as a lying-in asylum. But diseases will also be treated. The charges for treatment and board will be nominal. Those not able to pay anything will be treated without charge both in hospital and dispensary.

Dr. James Fitzgerald Feeley, Chief-Surgeon and President of the Board of Managers of St. Catherine's Hospital, Brooklyn, died suddenly on August 30th. He was born in London, England, in 1844, and came to Brooklyn when a child with his parents. He graduated from the New York University Medical College in 1865, and from 1868 to 1873 he was demonstator of anatomy in this institution. He was one of the founders of the Brooklyn Surgical Society, and was a member of the Kings County Medical Society, the New York Medical Association, the New York Physicians' Mutual Aid Association, etc., etc.

Dr. William H. Caemmerer died in Brooklyn on August 30th. He was born in the East Indies seventy-eight years ago. For eighteen years he was examining physician at Castle Garden, holding that position during the Civil War.

Dr. Cornelius H. Schapps, ten years ago a prominent physician of Brooklyn, died September 1st. He was eighty-two years old. He served for many years on the Brooklyn Board of Education, and was an energetic advovate of compulsory education.

Commissioner of Charities, Adolph Simis, Jr., for the Borough of Brooklyn and Queens, has completed his budget for the year 1900. An appropriation of $703,298 is called for. This is an increase of $371,004 over that of 1899. This increase is chiefly for alterations, repairs, and additions to the hospitals and almshouse plants in these boroughs.

Some physicians in this city are said to thrive on the practice of assisting rejected applicants for life insurance to get into such physical condition as will unable them to pass the usual examination and victimize the companies. Concerning this work the representative of a large company states that there are certain members of the medical fraternity of the variety that has lost all hope of attaining success by legitimate means who will for a monetary consideration, examine an applicant for insurance who is doubtful about his chances of success, find out his physical weakness, and put him through a course of treatment which will bolster up his frame and enable him to pass as a healthy man for the brief space of time in which the examination is made. On the other hand, there are few agents who will not exhibit the profoundest resentment against the physician who rejects the subject whom the agent may have been working for months to capture.

Three children were taken to the New York Pasteur Institute yesterday by their father, Adam Beckenbach, a hatter, living in West Orange, N. J. All three had been bitten on Sunday, August 27th, by a pet dog, that after inflicting severe wounds upon each of the children disappeared, and is still at large.

MEDICAL MATTERS IN CHICAGO.

[From Our Special Correspondent.]

POLLUTION OF WATER-SUPPLY——ANOTHER DEATH AT ZION HOME—EFFECT OF RAINFALL UPON CERTAIN KINDS OF DISEASES—INVESTIGATIONS REGARDING CHILD-STUDY IN CHICAGO PUBLIC SCHOOLS—INVESTIGATIONS AS TO THE BACILLUS ENTERIDITIS SPOROGENES (KLEIN).

CHICAGO, September 5, 1899.

ON August 21st two questions of the utmost importance to the general public and to the business and commercial interests of Chicago were considered in conference. Consideration of the first is expected to result in revision of the municipal code relating to the care and control of the streets and alleys, and to the general sanitary and police regulations of the city. The second problem arises from a recent order of the city against the pollution of the water-supply by dumping into the lake, and threatens most serious complications which may greatly delay the completion of the drainage-canal if they do not stop further improvement of the Chicago River. Among the evils discussed at the conference which are not adequately dealt with by the existing code are: Littering of the streets by private property owners; dumping refuse in the streets and alleys; leaving barn refuse on public or private property; street obstruction by standing wagons and cab-stands, or other similar violations of a dead-letter law; rag-picking or the handling of garbage or other refuse within the city limits except for the purpose of removal; location of rag-picking depots within the city; accumulation of refuse on private property.

Among the provisions needed are: Police regulation of hauling and teaming so as to prevent littering streets; garbage and refuse receptacles to be placed on private property, with regulations for cleaning them; rules and regulations prohibiting contractors and builders from unduly obstructing streets; special regulations for cleaning and sanitary care of South Water street, markets, etc.; law against dumping of filth and other material in catch-basins and in sewers in the street; regulation against dumping on private property; destruction of dangerous or objectionable weeds or thistles on private and public property.

Many proposed changes in the laws so as to secure their proper enforcement and the conviction of offenders were discussed. Regulations prohibiting objectionable noises at night received attention. Commissioner Reynolds called attention to the continuous blowing of signal whistles on the lake and along the railroads, which, he declared, is contrary to law and makes sleep impossible in many portions of the city. The advisability of putting all sanitary inspectors in uniform was also considered. Before adjournment it was agreed that each department should formulate its recommendations, to be submitted at the next meeting of the commission.

According to our local newspapers, people are constantly dying at Zion Home, Dowie's faith healing institution. Recently a child, nine years of age, unable to exercise any discretion of her own, was brought to Zion by her parents in response, it is said, to the solicitations of Dowie, with diphtheria, from which she died. In commenting on this case a local paper editorially remarks: "If human life is sacred, and if it is of any public concern whatever that it be safeguarded and preserved as far as practicable, then the public is concerned with the rites and practices of 'Zion' in Chicago. Unless the people are absolutely indifferent to the deaths of individuals through charlatanry and fraud, they have a vital interest in depriving Dowie's 'doctors' of some of their power to do harm."

It is a difficult matter to say that an adult person shall not, if he so desires, dispense with medical attendance and depend on faith to cure his disease, but it ought not to be a hard matter for the officers of the law to discourage the impostor from playing on his victim's superstition and persuading him to jeopardize his life. But when it comes to innocent children, incapable of deciding for themselves, and whose parents are under the duty of providing them with doctors and medicine in case of need, it ought not to be hard to apply an efficient legal remedy. The attorney for the State Board of Health says the board contemplates asking the next Legislature for a modification of the medical practice law that will make it impossible for Doweism to kill young children by neglect. The Legislature ought to make such a law, and make it strong.

The Health Department of Chicago has issued a bulletin setting forth some curious and interesting facts about the effect of rainfall upon certain kinds of disease. The first four months of 1898 were remarkably dry—especially April. The total precipitation for these months was only 4.5 inches, as against 9 72 in normal years. Drs. Reynolds and Reilly have discovered that this fact had a marked effect in decreasing all "water-borne" diseases, such as typhoid fever, while, on the other hand, it greatly increased the "air-borne" diseases, such as scarlet fever, pneumonia, and diphtheria. In the seventeen dry weeks the deaths from water-borne diseases averaged 25.7 per week. In the ensuing nine weeks, which were normally wet, the deaths from these diseases averaged 44.8 per week—an increase of 74 per cent. On the other hand, the air-borne diseases during the dry period caused 191 deaths per week, while during the ensuing nine weeks these deaths fell to a weekly average of 105—a decrease of 45 per cent. The same results are shown by a comparison of the 1899 dry season with the first six months of 1898, which constitued a wet season. During the first six months of the present year there were 317 deaths from scarlet fever, an increase of 750 per cent. over the previous year. But during the 1898 wet season the deaths from typhoid were greater than in 1899 by 82 per cent. The conclusion is that, in Chicago at least, "dry seasons increase the prevalence and fatality of the air-borne diseases and reduce the prevalence and fatality of the water-borne diseases, and vice versa." The pollution of the lake by the flushing of the sewers probably accounts for the effect of rain on the typhoid type of diseases. The completion of the drainage canal will bring an improvement in that regard. As for the "air-borne" diseases, they will have to be combated by keeping the streets and

alleys cleaner, and by improved sanitary precautions in tenements and residences.

Scientific pedagogy and child-study in Chicago's public schools recently received fresh encouragement and impetus when a special committee having charge of the work asked for $2000 to carry it on to the end of the present year. Assurance was received that the School Board would grant the request. Dr. W. S. Christopher, Chairman of the Special Committee, presented a long report of extreme interest in its revelations. This report covered experiments made with children of the Alcott, Burr, Hoyne, and an ungraded school as to their weight, height, endurance power, air, or lung capacity, grip (right and left hand), sight, and hearing capacities. In all about 1400 school children were examined during the last three months of the recent school year. Professor F. W. Smedley of the University of Chicago, and Professor C. Victor Campbell of the public schools conducted the experiments.

After a certain age is reached should the girls and boys of the public schools be separated in their school work and different tasks be assigned to each? This was one of the important questions propounded by Dr. Christopher in his report. The ergograph (the child fatigue-testing machine) showed in experiments with 1400 school children that the girl of sixteen and seventeen had far less endurance power than the boy of the same age, while from six to nine years of age the endurance power of the girl was the same as that of the boy. After nine the girl's endurance decreased, the boy's increased. Naturally, Dr. Christopher asked, should the same burden then be put upon the girl in school after nine years of age as upon the boy after the same period is passed?

In the ergographic test the child was required to lift with its middle finger seven per cent. of its actual weight for ninety seconds. The ergograph registered by tracings the endurance power of the child. Its use immediately revealed the neurotic child, the child of highly strung nerves and irregular capacity for work. Since the apparatus revealed this, it followed that such knowledge given to the teacher or a parent would at once suggest means of aiding the child, strengthening it where weakness existed. The ergograph revealed that endurance comes to the growing child quicker than age, but Dr. Christopher held that its most wonderful and valuable detection was the point which made it plain to him that after a certain age girls should not study with boys, nor carry in the school work the same burdens put upon the opposite sex.

In the test of the lung capacity of the children it was revealed that with advancing age the child's capacity increases, but after nine years the lung capacity of the boy is greater than that of the girl until at sixteen or seventeen there is a wide difference between their strength in this respect. The measurements for height revealed that there is an intimate relation between intellectual capacity and height. There are exceptions to the rule, it was admitted, but as a rule a child with normal height at a given age was of stronger intellectual capacity than a child of less height at the same age. The same rule was found to apply to weight. A child of healthful intellectual capacity was found to be of normal weight for its age. This led Dr. Christopher to suggest that the test for the first admission of children to school should be upon their weight, and not their age, as at present. As to the grading of children in the schools, it might well be done upon physical characteristics as well as intellectual ones. He added: "If our observations could have covered more children, say 5000 or 10,000, we would be in position to formulate a positive rule upon what we have discovered and at the same time we would be able to study and account for exceptions to the rule. It is a duty of the Board of Education to do no physical damage to the children while aiding their intellect. We found that the weights of the children in the first grade varied but little, but at the seventh and eighth grades the variation was great."

Investigation was made of how the strength of the child varied during school hours—at nine quite fair, at ten strong, at eleven decreasing, and at noon gone; a slight revival at one, fairly good at two, and a second decline at three. Closer study along this line would reveal a means of knowing just what the strength capacity of each child was during the hours of work.

Tests were made of the dull, stupid, and unmanageable children of an ungraded school. In every particular but lung capacity they fell below the well-fed and disciplined children of the Alcott School. This led Dr. Christopher to comment that further investigation would reveal how to care for the unmanageable children of the ungraded schools, how to correct them and develop their best parts. He asked that the board authorize the continuance of the work for the remainder of the school year, create a special department for it, choose a supervisor and give him at least two assistants. The cost for carrying on the work the remainder of the year would be $2000. For a full school year such a department, he thought, would not cost over $5000 or $6000.

Dr. Adolph Gehrmann, the Director of the Municipal Laboratory, Chicago Department of Health, has been conducting a series of investigations in regard to the bacillus enteriditis sporogenes (Klein), with a view to determine the presence of this bacterium in Chicago's sewage and of studying its relations to polluted drinking-water. His observations have so far been confined to Chicago River water and sewage taken direct from the sewers, and to the samples of city water-supply collected in making the daily analyses for the Department of Health. From these experiments it appears certain that bacteria of the species described by Klein, or very similar to them are practically always present in the sewage of this city. He is not, however, ready to admit that all of the animals inoculated were killed by the bacillus enteriditis sporogenes, but it is at least clear that the group of bacteria to which this species belongs is present. Klein suggests the use of the Pasteur filter as an aid to isolating the spores from water. But in practical water examination Dr. Gehrmann has found that the extra work and care involved in arranging for filtration in this manner are not repaid by the results.

CORRESPONDENCE.

AN ANOMALOUS CONTINUED FEVER.

To the Editor of the MEDICAL NEWS.

DEAR SIR:—During the past year or two, especially in North Carolina, much has been said in regard to the existence of a type of continued fever different from malarial and typhoid fevers. The subject was before the last meeting of the State Medical Society, and the general opinion was that we find but two forms of fever, *viz.*, malarial and typhoid fevers. This opinion is hard for us, who have met many cases so different from the usual forms of these fevers, and with so very few characteristic cases of malarial or typhoid fever, to believe.

For the past five years in the town of High Point, N. C., with a population of 5000, I have met many cases in which, owing to the lack of the usual symptoms of even mild typhoid fever seen in other localities, I have not been satisfied to accept this diagnosis; and owing to my inability to find any form of the malarial plasmodium, malarial fever was not an acceptable diagnosis; especially when the liberal use of quinin had failed to impress the disease. I have made Widal's test in many cases and have never been able to obtain the characteristic clumping of the bacillus, nor has Dr. Messick of Baltimore, who has kindly made a number of examinations of blood from these patients, succeeded in finding any form of malarial germ. The usual symptoms in these cases are malaise, loss of appetite, tongue slightly coated, temperature from 100° to 103° F. Most patients when first seen have a tendency to constipation, but if allowed to eat solid food, diarrhea develops. The patients generally are free from fever in from three to four weeks, some in two. A very peculiar feature met with is that a large number of cases continue as long as twelve weeks before fever is gone; and many of these patients have gone through three attacks in three successive years. Some of them have refused to go to bed after the first attack, and have apparently progressed as well as, or even better than, those who did. I have seen these patients at all times during the attack, and at no time found them without fever. They have been carefully examined for diseases of the lungs, etc., but with negative results. No age seems to be exempt. I have seen it in children and aged alike. One lady seventy-six years old went through an attack of twelve-weeks' duration. Treatment has no effect on the course of the disease. I have seen but one death among several hundred cases, and in this instance no post-mortem could be obtained.

JAS. S. TURNER.

HIGH POINT, S. C., August 28, 1899.

For Vaginitis.—

GASTRIC ORIGIN OF DERMATOSES—AORTITIS OCCURRING IN MALARIA—TUMOR DUE TO COCCIDIA—A NEW CLASS OF MERCURIAL ANTISEPTICS CALLED EGOLS—IMMUNITY IN THE BLOOD OF THE FETUS TRANSMITTED FROM THAT OF THE MOTHER—HYSTERECTOMY IN PUERPERAL INFECTION—INCREASE OF TYPHOID FEVER IN PARIS—INTRA-ABDOMINAL TENSION IN ASCITES.

AT the Academy of Medicine, Paris, July 18th, ROBIN spoke of the gastric origin of a certain number of dermatoses. He made a study of 422 dyspeptics, of whom 129 presented some skin lesion (acne, eczema, lichen, pruritus, urticaria, hyperidrosis, furunculosis, seborrhea, alopecia, recurrent herpes, and squamous dermatitis). Thirty patients who suffered from simple pruritus or eczema, part of whom did not present any symptoms of stomach trouble, were also carefully examined. There was found in all, however, a certain amount of lactic- or butyric-acid fermentation. The latter acid was found in the gastric contents of 28 of the 30 patients, whereas it was found only 31 times in the gastric contents of 100 hyperesthenics chosen at random. These examinations, therefore, show that there is a constant relation between pruritus and fermentative dyspepsia. The acids seem to act directly upon the skin already modified by improper nutrition. Possibly they are eliminated through the sweat-glands. The dyspepsia should be attacked by appropriate measures and the nutritive disorders should, if possible, be removed. The fluorids should be given for lactic-acid fermentation while for the butyric the double iodid of potassium and cinchonidia, sulphur, iodid of sulphur, etc. Locally, the various well-known remedies may be used with success. Chlorid of sodium and calcium carbonate in the powdered form are helpful. The powder should be dusted on, and then an application should be made of a balsam containing aloes.

On July 25th POTAIN reported the case of a man, aged twenty-five years, whom he had received into the hospital suffering from intermittent attacks of fever which yielded to treatment by quinin. He gave a history of malaria some years previous. There was a marked increase in the area occupied by the arch of the aorta and this symptom subsided with the disappearance of the malarial symptoms. It is possible to look upon this condition as the result of a paresis of infectious origin, but it is by no means an invariable accompaniment of malarial infection. Whether or not it was a true inflammation of the aorta deserving the name of aortitis, it seems probable that such a marked change in the arterial wall cannot take place without a certain modification of the tissues. It seems similar to those lighter degrees of aortitis which have been observed in the course of various infectious maladies.

CORNIL examined a tumor the size of an orange which had developed in a bursa under the right triceps following a blow. Some time afterward similar tumors appeared over the right and left great trochanters and then an other appeared near the left olecranon. They were situated either

in the serous bursæ, subcutaneous or deep, or in the cellular tissue under the muscles, but in no instance did they communicate with the neighboring joint-cavity. To the naked eye these tumors were made up of a great number of pockets of various sizes so that they resembled a sponge. Each of these pockets contained a yellowish-brown fluid, creamy or viscid, in which there were yellow grains of calcareous material. The general location of the tumors, together with the fact that the patient's sixteen-year-old brother presented one of the same nature, led to the inference that they were of parasitic origin. This hypothesis was supported by the demonstration in the tumor substance of numerous giant-cells, but no parasites could be found. Recently, however, Milian, who made an examination of a similar tumor removed from the sole of the foot of a girl aged eight years, found it to contain oviform, refractive, crystalline bodies. Some of these had capsules and stained deeply with hemotoxylin. These observations prove the existence in a man of a variety of tumors of the cellular subcutaneous tissue having peculiar characteristics and produced by coccidia.

At the Academy of Science July 10th, GAUTRELET described the manufacture and characteristics of a class of new antiseptics. They are prepared from the parasulphonal derivatives of the phenols by the action of nitric acid. He found that orthonitroparasulphonic acids under certain circumstances will absorb a quantity of mercury equal to a half atom per atom of the original phenol made use of in the reaction. There result some very stable compounds to which he gave the generic name egol. The egols occur in the form of a reddish-brown powder, soluble in water in all proportions, either hot or cold, but insoluble in concentrated alcohol. The watery solutions of the egols are without odor and have very little taste. They do not coagulate albumen, are not decomposed by organic matters nor are they caustic or irritable. They are not very poisonous. It requires at least two parts in the thousand of the body weight of an animal to produce death, when injected hypodermically. The egols are quickly eliminated from the system. They possess a considerable antiseptic power. In the proportion of four parts to one thousand they stop all bacterial action.

At the session of July 24th BECLERE, CHAMBON, MENARD, and COULOMB described experiments made by them to determine the transmission of immunity from smallpox, from the mother to the child. They found that women who were vaccinated during pregnancy and whose blood-serum was found to possess antivirulent properties with reference to smallpox transmitted this condition to the blood of the fetus. On the other hand, there was no such transmission from those mothers whose serum was not antivirulent whether they were vaccinated during or before pregnancy.

At the Surgical Society, July 26th, TUFFIER spoke of vaginal hysterectomy in acute puerperal infection, an operation which he has performed three times upon patients in whom the lesions of the disease were confined to the uterus. In each instance curetting and various other measures in ordinary use had failed and the patient was considered doomed. One of these women made a rapid recovery; the other two died. A search through medical literature shows that since the operation was first performed by Schultze in 1886 there have been thirty-three hysterectomies performed for infection. In twenty cases it was followed by death; in thirteen by recovery. Vaginal hysterectomy under such circumstances presents great difficulties. On account of the softness of the uterine walls, it is almost impossible for the operator to make out the exact limits of that organ.

At the Medical Society of the Hospitals, July 21st, NETTER spoke of the marked increase in the number of patients of typhoid fever at the Trousseau Hospital since the beginning of the year. As the patients were all children the infection most likely took place in their homes or their immediate vicinity. He expressed the opinion that the contamination of the drinking-water at its source was not likely. It was more probable that it became foul either in the reservoirs or in the pipes. It was also necessary in determining the source of infection to consider the increased amount of digging in the subsoil which had taken place.

At the Biological Society, July 15th, PITRES spoke of the intra-abdominal tension in ascites. This he usually found to be less than twenty millimeters of mercury. The initial pressure when the abdomen is tapped is not directly proportional to the quantity of liquid accumulated in the peritoneal cavity. The final pressure after evacuation of the ascitic fluid ordinarily remains positive. Sometimes it sinks to zero but it never falls below that point, probably on account of the elasticity of the abdominal walls and the compressibility of the gas contained in the intestines. The total value of tapping, that is to say, the difference between the pressure in the beginning and at the end of ascites, is never very great. It was found to range from three to nineteen millimeters of mercury, but it rarely surpassed fifteen millimeters.

SOCIETY PROCEEDINGS.

ROCKY MOUNTAIN INTERSTATE MEDICAL ASSOCIATION.

First Annual Meeting, Held at Salt Lake City, Utah, July 25, and 26, 1899.

AFTER the opening of the meeting by the President, DR. CHARLES PINCKNEY HOUGH, and an address of welcome by the HON. HEBER M. WELLS, Governor of Utah, DR. SALATHIEL EWING of Salt Lake City read a paper, entitled

THE MEDICO-LEGAL SUPERVISION OF PROSTITUTION.

He urged the dangers of syphilis and gonorrhea, and said that since prostitution cannot be eradicated it should be supervised so as to lessen the ravages of these diseases. The attitude of the police authorities toward the class of prostitutes was condemned. Funds obtained by the licensing of prostitutes could be rightly employed for the limitation of the diseases in question, by the support of reformatory institutions and hospitals. Weekly inspection

should be practised, and strict quarantine and hospital treatment of those diseased carried out. While he entertained the highest respect for the clergy, he thought that in regard to this matter, they had generally taken a wrong attitude.

TREATMENT OF CHOREA.

DR. S. D. HOPKINS of Denver read a paper with this title. He had obtained satisfactory results by the administration of antipyrin according to the method of Dr. J. T. Eskridge. The drug was given in increasing doses, beginning with 1 grain for each year of the child's age and increasing 1 grain each day. In the mildest cases the child was permitted to sit up a part of the day and the antipyrin was only given in the evening. In severe cases absolute rest in bed was required and the dose of antipyrin was given three times a day. As soon as the choreic movements ceased, or greatly diminished, the drug was stopped. Fowler's solution and iron were given until two or three weeks after the cure appeared to be complete. In giving such doses of antipyrin, 20 grains, three times a day to a child eight years old, for instance, certain precautions must be observed. The child must be kept in bed and carefully watched. If there is heart disease, or fever, antipyrin should not be given. The speaker had seen no bad results from its use, and in the nineteen cases upon which his paper was based had obtained rapid cures.

HYDATID MOLE.

DR. S. G. KAHN of Leadville reported a case of hydatidiform mole or cystic degeneration of the chorion from his own practice, with three other hitherto unpublished cases from the practice of others. He had sent letters of inquiry to 400 physicians, from whom he received 78 replies, reporting 12 cases in all. This illustrates the rarity of the disease, and the impossibility of obtaining any valuable statistics. The results of inquiries with regard to factors of causation had been negative.

HEMOPHILIA.

Two cases of this affection were reported by DR. A. A. KERR of Salt Lake City. One was in a boy ten years of age, who bled from an abrasion of the gum. His mother's brother had died of hemorrhage following an operation. The parents were healthy, as were two of their children. Two other children had been bleeders, dying from hemorrhages at the age of twelve days and six months, respectively. The second case was that of a baby ten months old, whose family history was negative.

The president's address, delivered at the opening of the afternoon session of the first day, emphasized the need for closer association among the physicians of the inter-mountain States. They have many themes of common interest, and are too far removed to attend the regular meetings of the American Medical Association when held at the East. They can meet each other once a year at some place in the inter-mountain region with great advantage. He advocated proper regulation of the practice of medicine, but thought that medical laws should be so modified as to permit a physician of established fitness to practise in any State without having to pass an examination which some of the examiners might have been able to pass only when they first graduated. If membership in the American Medical Association were not a sufficient guarantee of fitness to practise anywhere, that organization ought to be reorganized.

USE OF THE HEMATOKRIT.

DR. JUDSON DALAND of Philadelphia urged the clinical value of blood examinations with this instrument. He pointed out the great amount of time required to make a careful blood-count, the importance of duplicating it to obtain reliable data, and the great probability of serious inaccuracy. The hematokrit does not exactly replace the blood-count, but the ease with which the volumetric estimate of the corpuscles can be made gives it a greater clinical value. More time is required to keep the apparatus clean and in order, but with an assistant the volumetric estimate could be made in three minutes. A diluting fluid to prevent coagulation is not needed unless the tendency to coagulate is very great, but rapid manipulations are necessary to secure accurate results. The speaker revolves the tube 10,000 times per minute for two minutes. This gives 50 per cent. as the volume of corpuscles in normal blood. By multiplying by two the percentage of corpuscles as compared with normal blood taken as 100 per cent., is obtained. For comparison with blood-counts the 100 per cent. so obtained may be taken as representing 5,000,000 corpuscles to the cubic millimeter.

FIBROID PHTHISIS INDUCED BY QUARTZ DUST.

DR. W. W. BETTS of Salt Lake City called attention to the terrible mortality in connection with lung trouble induced by the dust of the De La Mar mill, where certain gold-bearing ores are reduced to a fine powder and the air is filled with an impalpable dust. It was stated that all who had worked in these mills from seven to nine months, previous to January, 1898, are now dead. The total deaths up to March 1st, of the present year he believed to be 166. He reported 14 cases in tabular form, occurring in men from twenty to forty-three years of age, who previously were healthy. One was able to work 23 months and had lived 2 years afterward. Another had worked but 3 months and died 7 months later. The average time they were able to continue working was 13 months and the average time they lived after leaving the mill was 10 months. The trouble began with attacks of acute bronchitis with inflammation of all the exposed mucous membranes. Later there was loss of appetite and loss of weight, rapid respiration and general malaise. The pulse ranged from 90 to 120, and became weak and intermittent, and in the late stages the temperature rose to 102° or 104°F. Two autopsies showed great disease of the pericardium, the lung tissue was excessively firm with great increase of connective tissue, and air-cells partly obliterated. On chemical analysis the lung tissue was found to contain 2.8 per cent. of silica, and the bronchial glands 3.8 per cent. There is tellurium in the ore but no arsenic.

DR. P. E. JONES of Salt Lake City thought the disease

in question is the same as that which affects the employees in cutlery-works and grindstone quarries, and to which grain-shovelers are especially liable. So long as life is less valuable than gold will the sacrifice continue.

Dr. F. Clift of St. George, Utah, said all the men who left St. George to work in that mill came back with this trouble. Three of them are still alive but on the way to follow their fellows. There is not the slightest doubt that all who now work in the mill are likewise doomed.

Dr. Mayo, who had been surgeon for the De La Mar Company for four years, had carefully investigated the subject with the aid of the Company's records, and had found that only 34 had died who had been employed during that time. He believed a similar mortality would be discovered among the workers in other mills handling similar ores. When the disease is once contracted it probably is necessarily fatal. Since the attention of the company had been called to the matter extensive changes had been made in the mills. Fans, hoods, and ventilators have been put in and respirators supplied to the men with instructions about using them. Recently an inspector of the New York Life Insurance Company had reported that the workers in these mills are in no more danger than the workers in the flour-mills of Minneapolis.

REPEATED EXTRA-UTERINE PREGNANCIES.

Dr. C. K. Fleming of Denver reported two cases. The first patient, after marked evidence of rupture of the sac, had presented the symptoms of sepsis and was treated three weeks for typhoid fever before Dr. Fleming saw her. She promptly recovered after the evacuation of a pelvic abscess. After eighteen months of regular menstruation she had the same train of symptoms but refused operation and slowly recovered without it. The second patient was operated on shortly after the occurrence of symptoms of tubal rupture, and a pelvic hematocele found. One year later similar symptoms appeared, and at operation the right tube was found ruptured and containing a large blood-clot. This patient also recovered. There was no history pointing to previous disease in either case.

CARCINOMA OF THE UTERUS.

Dr. W. W. Grant of Denver pointed out that the universal increase in the mortality from cancer makes its causation and prevention of practical interest. The theory of a specific parasite seems on the whole to be gaining ground. Certain it is that cancer occurs chiefly in parts most exposed to both traumatism and infection. On early diagnosis rests the only chance of cure. He favored frequent examinations of women near the menopause, and microscopic examinations of suspicious lesions. In women who have borne children all lacerations of the cervix should be repaired at forty years of age.

TREATMENT OF ACUTE CONJUNCTIVITIS.

Dr. Edward Jackson of Denver said that acute conjunctivitis includes, in addition to the effects of eye-strain and local irritants, at least five specific infections; and that successful treatment depends on the careful discrimination between the different classes of cases. Eye-strain is always to be thought of and eliminated. In all forms of conjunctival infection, complete cleansing at sufficiently short intervals is of the greatest importance. Protargol is to be employed for purulent conjunctivitis, with a few applications of a strong solution of silver nitrate in bad cases. Mydriatics and cocain should not be prescribed for acute conjunctivitis, because they are more likely to do harm than good. To secure the greatest cleanliness of the conjunctiva and to limit the dangers of infection all forms of poultice, bandage and compress should be carefully avoided.

POINTS IN EYE-WORK.

Dr. R. F. LeMond spoke of the important relations between eye lesions and brain disease. He believes the pathological changes often found in the astigmatic eye are for the purpose of relieving the strain that would otherwise come upon the brain.

IMPROVED ARTIFICIAL EYES.
